Of course, no evaluation of pulmonary symptoms is complete without a detailed history of smoking habits. The physician should ask, “Have you ever smoked?” A negative answer should prompt a confirmatory response such as, “So you are a lifelong nonsmoker?” and a compliment if the second answer is yes. If the patient has smoked, the next questions should be, “When did you start?” “When did you quit?” and “How much did you smoke while you were at it?” Ask also about different forms of tobacco and exposure at home or workplace to other people’s tobacco smoke. A history of exposure to environmental smoke is also important.⁵³ In many developing countries, smoke from indoor cooking and heating fires is a major cause of lung disease, especially in women. Risk factors for *human immunodeficiency virus* (HIV) infection, such as unprotected sexual activity and injection drug abuse, should be specifically queried.

Medications and Allergies

A complete list of all medications is essential to a thorough history. Ideally, the patient should bring in all his or her medications, and the physician should carefully go through each one, checking that the prescription has been properly written and filled and that the patient understands the benefit and possible side effects of each medicine. It is vital to note whether the patient has ever had an allergic or toxic reaction and what these reactions were. A complete listing of supplements and herbal medications should also be recorded and reviewed for potential interactions with conventional medications. No drug history is complete without assessing whether the patient drinks alcoholic beverages or uses illicit drugs. The amount and frequency of their use should be recorded.

Occupational History

The occupational history, which is often included as part of the social history, is an integral part of a thorough medical interview. Identifying a relevant occupational exposure may provide the only opportunity to remove the patient from the exposure and prevent progressive and irreversible lung damage. Moreover, identifying injurious occupational exposures can facilitate justifiable compensation for the patient and removal of the hazardous materials from the workplace by the industry.

The evaluation of suspected occupational lung disease is discussed in Chapters 64, 72, 73, and 74. Although only a few questions are asked in most initial medical interviews, if occupational illness is seriously being considered, a detailed inquiry about each industry, profession, and job the patient has held needs to be performed.^{54,55} Because there are so many environmental agents and different associated

illnesses, the diagnostician should consult online resources such as the National Institute for Occupational Safety and Health, the Environmental Protection Agency, Hazardous Substances Data Bank, the Occupational Safety and Health Administration, or other online resources to learn more about the putative environmental toxin.^{56,57}

Travel History

Previous places of residence help diagnose endemic fungal diseases, especially histoplasmosis and coccidioidomycosis. A history of recent travel may help establish the possibility of exposure to infectious diseases that are restricted to specific geographic regions.⁵⁸ The physician should inquire into the duration of travel. Long trips by air or car increase the risk for deep venous thrombosis and venous thromboembolism, which are reported in up to 10% of passengers on long-haul flights.⁵⁹ It is important to consider events after travel: symptoms of pulmonary thromboembolism and infarction may arise a variable time after the inciting event. The epidemic of *severe acute respiratory syndrome* (SARS) in southeast China in 2002 and its rapid spread throughout the world by airline passengers emphasizes the importance of obtaining a careful travel history.

PAST MEDICAL HISTORY

Previous illnesses may recur (e.g., tuberculosis), and new diseases may complicate old ones (e.g., bronchiectasis as a sequela of necrotizing pneumonia). Information about previous illnesses, operations, intubations, and trauma involving the respiratory system may be essential to understanding the current problem. Although these data may be gathered as part of the past medical history, much of the pertinent information will be absorbed into the chronological sequence of the history of present illness. Prior chest radiographs are an important aid in the evaluation of any abnormal chest radiograph because of the insights they provide into the duration and trajectory of illness. Patients should be asked to bring in previous films, but if they are unavailable, physicians should make every effort to obtain them, because old radiographs may save needless, costly, and sometimes risky interventions.

INFORMATION FROM QUESTIONNAIRES AND OTHER SOURCES

Printed or computer-based questionnaires and histories taken by nurses or allied health professionals are often used to expedite history taking. They can identify problems that can be explored further in the medical interview, and they facilitate a focused yet comprehensive evaluation. Occupational questionnaires have been shown to enhance recognition of occupational illness and correlate well with the findings of an industrial hygienist.⁶⁰ Computer-based interviews can gather more information, allow more time to complete the interview, uncover sensitive information, and may be adaptable to the hearing impaired and to persons speaking a language different from that of the physician.⁶¹

These forms of information gathering should be considered adjuncts and not a substitute for the thorough history taken by the physician. The limitations of the programmed questions are that the patient may not understand or be

able to express her or his concerns when confined by a form that does not allow the free exploration of symptoms that the open interview does. Automated data collection, of course, lacks the benefits gained from the patient-physician interaction, such as the establishment of rapport and the ability to observe nonverbal behavior. The interview itself also provides both time and opportunity for the physician to fully comprehend the patient's illness and to contemplate the primary and differential diagnoses.

For monitoring the course of certain disorders such as asthma, daily recording of symptoms, such as wheezing and breathlessness, and objective assessments of severity of disease, such as peak expiratory flow, in a diary are preferable to a single questionnaire because recall of symptoms may be faulty and one measurement may not be representative. The electronic monitoring that now comes as standard equipment with most home noninvasive ventilation devices gives the date and time of the respiratory events and the use of these devices.

PHYSICAL EXAMINATION

Sadly, the declining emphasis on proficiency in physical examination during medical school and residency training and the ever-increasing reliance on technology-based diagnosis have led to a decreased interest in, some say even the "demise" of, the physical examination.⁶² However, the old observation that 88% of all diagnoses in primary care were established by taking a thorough medical history and performing a complete physical examination⁶³ probably still holds today. At the very least, a carefully executed history and physical lead to more intelligent and cost-effective use of diagnostic technology. Plus, a physical examination can be performed virtually anywhere, may provide important information, lends itself to serial observations, and increases patients' confidence in their physicians.

EXAMINATION OF THE CHEST

Physical examination of the chest employs the four classic techniques of inspection, palpation, percussion, and auscultation. Each is described subsequently, as are the constellations of abnormalities that allow the examiner to infer the presence and type of various pulmonary disorders. Apart from inspection, which is not only a visual but also sometimes an olfactory tool and is always a structured cognitive skill, the other three modalities depend on the generation and the perception of sound or tactile sensations and vibrations. As was true of the history, the environment in which the physical examination takes place must be appropriate to the needs of both the examiner and the examined. Privacy, warmth, good light, and quiet are all essential. The best light source is natural sunlight, which should be used if possible. An ill-lit, noisy, or distracting environment will likely result in a physical examination that is flawed or incomplete.

Inspection

The physical examination begins the moment the clinician first sees the patient, even before the introductions and beginning the medical interview. Keen observations, and

the ability to pursue and interpret these observations, are the keys to skilled clinical diagnosis.

Inspection of the chest is carried out after sufficient clothing has been removed and the patient has been suitably draped to permit observation of the entire thorax. Ordinarily, inspection is performed with the patient sitting, but if the patient is too weak or cannot sit unaided, he or she should be supported in this position. Observing the shape and symmetry of the chest allows such abnormalities as kyphoscoliosis, pectus excavatum, pectus carinatum, ankylosing spondylitis, osteoporosis, gynecomastia, and surgical scars or defects to become obvious.

Several classic patterns of ventilation can be readily recognized (Fig. 16-1). Examples are *tachypnea*, which is almost uniform rapid shallow breathing; *Kussmaul breathing*, which is relentless, rapid, and deep breathing (air hunger); *Cheyne-Stokes respirations*, a cyclical waxing and waning of the depth of breathing with regularly recurring periods of apnea; and *Biot breathing*, which is totally irregular breathing, both the size of breaths and the periods of apnea, which are sometimes prolonged. Impending respiratory failure from muscle fatigue can be detected by observing rapid shallow breathing, abdominal paradoxical motion, and alternation between rib cage and abdominal breathing, so-called *respiratory alternans*.⁶⁴ The Hoover sign is the paradoxical inward displacement of the costal margin at the end of inspiration or throughout inspiration. Decreased regional ventilation can be detected by seeing a lag in the motion of the affected part of the chest wall during breathing.

Palpation

Palpation of the thorax is a necessary part of the cardiac, breast, and lymph node examinations and often can detect

bony abnormalities, such as a cervical rib, and subcutaneous calcinosis seen with systemic sclerosis. It is essential in examining causes of pain to determine point tenderness and thoracic spinal tenderness. It can detect fluctuant areas associated with empyema necessitans and crepitant areas associated with subcutaneous emphysema. Location by palpation of the trachea in the suprasternal notch is a useful way to detect shifts of the mediastinum. A spastic, extrafirm-feeling back muscle recognized by palpation may identify the cause of thoracic pain. A lag in movement of the chest wall, suspected from inspection, can be confirmed by placing the two hands over opposite portions of each hemithorax and both feeling and observing whether or not the thorax moves symmetrically.⁶⁵ Symmetry is as important in palpation as it is in inspection.

A palpable vibration felt on the body, usually over the chest, is called *fremitus*. Vocal fremitus is elicited by having the patient speak “one, two, three,” while the examiner’s two palms or sides of the hands are moved horizontally from top to bottom of the two hemithoraces. Vocal fremitus is increased over regions of lungs through which there is increased transmission of sound, for example, consolidation from pneumonia. Conversely, fremitus is decreased in conditions in which sound transmission is impaired, for example, pleural effusion. Occasionally, fremitus over part of the chest wall can detect the presence of airway secretions (rhonchal fremitus) or an underlying pleural friction rub (friction fremitus).

In examining the heart the examining physician should always search for an apical impulse, heaves and lifts, thrills, and palpable valve closure. In patients with severe COPD, abnormal cardiac movements are often better felt in the subxiphoid region than over the precordium.

Figure 16-1 Schematic drawing of waveforms in different patterns of breathing. (Adapted from Wilkins RL, Hodgkin J, Lopez B: *Lung and heart sounds online*, St. Louis, 2011, Mosby.)

Percussion

Skillful percussion depends on a uniform free and easy stroke of the striking finger (plexor) on the finger being struck (pleximeter), the ability to sense minor changes in pitch, and a keen sense of vibration—although the percussion note is heard, it is predominantly felt. Percussion of the thorax over normal air-containing lung produces a resonant note.

Sounds and tactile perception from percussion vary depending on the thickness of the skin, subcutaneous layer, breast tissue, and chest wall, as well as on the quality, distribution, and tension of the air under the area percussed. Pathologic processes may impair or enhance the resonating quality of the thorax. For example, the percussion note over a large pneumothorax is hyperresonant and becomes tympanic when tension is present; in contrast, percussion over a pleural effusion or pneumonia produces dullness, which has been defined as a low-intensity sound of short duration, feeble carrying power, and rather high pitch.⁶⁶ Flatness is the unresonating sound obtained by percussing over the liver. Three different tonal zones can thus be detected when percussing large pleural effusions: normal resonance above the fluid, dullness in the middle, and flatness when completely below the fluid; these variations in sound may result from the presence of an internal meniscus or fluid wedge, which points upward into the lung above it. Carrying out a thoracentesis in the dull area offers the best chance of obtaining pleural fluid and avoids puncturing either an abdominal viscus or air-containing lung.

Auscultation

A stethoscope draped around the neck has long been the badge of the medical professional, and it is worn with pride by physicians, nurses, and respiratory therapists, despite predictions such as “it, too, will someday be relegated to a museum shelf.”⁶⁷ This will not happen for a long time, according to Murphy,⁶⁸ who mounts a spirited defense of stethoscopes backed up by analyses of breath sounds obtained by respiratory acoustic recording. Indeed, there is now a body of literature on computer-assisted mapping of breath sounds using both recording and imaging techniques which provides new insights into their origin and

clinical significance.⁶⁹⁻⁷¹ For example, computerized multi-sensor breath sound imaging has proved to be a sensitive and specific tool for differentiating pneumonia or pleural effusion from normal lungs.⁷² Similarly, signal analysis of heart sounds recorded by digital electronic means has promising clinical applications and is useful for teaching cardiac auscultation.⁷³ The fundamentals of lung auscultation in physical examination have been reviewed recently.⁷⁴

Stethoscopes are also helpful in picking up wheezes in asthmatics and crackles in patients with interstitial lung disease whose chest radiograph findings are normal. Moreover, patients expect their physicians to listen to their hearts and lungs if they have cardiorespiratory complaints.

Like any piece of medical equipment, there are a number of available choices, and the design and care of the stethoscope may have a substantial impact on its performance. Electronic models promise ambient noise reduction and audio amplification, features that have been shown in randomized trials to provide statistically significant improvements in acoustics, especially in noisy environments.^{75,76} However, the magnitude of improvement is small relative to the best acoustic stethoscopes, and electronic stethoscopes have not been shown to improve trainee performance.⁷⁷ Sound quality with any stethoscope can be substantially degraded by failure to maintain the integrity of the rubber fittings, and prolonged contact of the tubing with the skin when worn around the neck can lead to hardening of the tubing and decreased performance. In any case, the stethoscope must be kept clean because it is increasingly recognized as a vector of nosocomial infection.⁷⁸

The terminology of breath sounds has been standardized and simplified to enhance understanding and communication (Table 16-2). Although a standardized nomenclature has been proposed by the American Thoracic Society⁷⁹ and the Tenth International Conference on Lung Sounds,⁸⁰ communication at the bedside often strays from recommended terminology.

The basic technique of auscultation with an ordinary stethoscope is well known to most physicians: the diaphragm detects higher-pitched sounds, and the bell detects lower-pitched sounds, although if the bell is tightly pressed against the body, the taut underlying skin itself may serve

Table 16-2 Classification of Common Lung Sounds

	Acoustic Characteristics	American Thoracic Society Nomenclature	Common Synonyms
Normal	200-600 Hz Decreasing power with increasing Hz 75-1600 Hz Flat until sharp decrease in power (900 Hz)	Normal Bronchial	Vesicular Bronchial Tracheal
Adventitious	— Discontinuous, interrupted explosive sounds (loud, low in pitch), early inspiratory or expiratory Discontinuous, interrupted explosive sounds (less loud than above and of shorter duration; higher in pitch than coarse crackles or crackles), mid- to late inspiratory Continuous sounds (>250 msec, high-pitched; dominant frequency of 400 Hz or more, a hissing sound) Continuous sounds (>250 msec, low-pitched; dominant frequency < 200 Hz, a snoring sound)	Adventitious Coarse crackles Fine crackles Wheezes Rhonchi	Abnormal Coarse crackles Fine crackles, crepitation Sibilant rhonchus, high-pitched wheeze Sonorous rhonchus, low pitched wheeze

as a “diaphragm” and improve perception of higher pitches. Conversely, the bell should be applied very lightly to hear, for example, the low-pitched rumble of mitral stenosis. Full contact with the skin is necessary for best listening, which may pose a problem in a patient whose intercostal spaces are sunken from weight loss. In addition, the skin or hairs may brush against the diaphragm and produce a sound that resembles a pleural friction rub. As with examiners’ hands, a warm stethoscope head is appreciated by patients. The importance of a quiet room and of applying the stethoscope directly to the skin rather than through clothing has recently been reemphasized.⁸¹ At times, especially in the intensive care unit, it is not always possible to sit patients up to listen carefully to their backs, which compromises the completeness of auscultation.

This chapter includes links to audio recordings, some with animations. To hear the recorded lung sounds at their intended pitch and intensity, it is recommended that readers listen through a stethoscope, with the chest piece held 4–5 inches from the audio speaker.

The recommended terminology for the ordinary breathing-associated sounds heard with a stethoscope placed on the chest of a healthy person is *normal lung sounds*, but, as shown in Table 16-2, many physicians prefer the older term *vesicular breath sounds* (Audio 16-1). The usually predominating inspiratory component arises from sounds generated by turbulent airflow within the lobar and segmental bronchi, whereas the weaker expiratory component arises within the larger, more central airways.⁷⁹ Sounds are attenuated as they move peripherally along the air passages and are further damped by the large volume of the lungs’ air spaces. The intensity of normal breath sounds varies with the magnitude of regional ventilation and, like percussion notes, diminishes with increasing thickness of the tissue overlying the chest wall. There is considerable variation among persons in the quality of breath sounds, which makes it essential to compare breath sounds from one side with those heard over the same location on the opposite hemithorax.

The transmission of normal lung sounds to the chest wall in pathologic conditions may be either attenuated or exaggerated. When the lung parenchyma is consolidated and the airway leading to the involved region is patent, breath sounds are well transmitted to the chest wall and are termed *bronchial breath sounds* (Audio 16-2). Bronchial breath sounds are loud, high-pitched, tubular, or whistling sounds with expiration as loud as or louder than with inspiration. Bronchial breath sounds are similar to *tracheal breath sounds* (Audio 16-3), and their presence is the classic auscultatory sign of pneumonia with consolidation. Similar sounds are heard in patients with other types of consolidation, such as pulmonary edema and hemorrhage. The presence of this sign assumes that the sounds originate centrally and reach the chest wall.⁸²

Interposition of a sound barrier between the central airways where sounds originate and the chest wall where

they are heard also attenuates or interrupts transmission of normal lung sounds. Accordingly, normal breath sounds are diminished or absent over a pleural effusion, pneumothorax, and peripheral bullae, or distal to an obstructing mass lesion. Conversely, they may be increased if chest wall deformity or bronchial or tracheal derangement allows movement of air to be closer than usual to the stethoscope.

Adventitious Sounds

The major types of adventitious sounds are classified in Table 16-2. Two generic categories of adventitious sounds have been documented by high-speed recording techniques, and each of these has two subdivisions: discontinuous sounds, including fine crackles and coarse crackles, and continuous sounds, including wheezes and rhonchi.⁸³

Discontinuous Sounds (Crackles)

Crackles, still often referred to as “rales” in the United States and “crepitations” in Great Britain, consist of a series of short, explosive, nonmusical sounds that punctuate the underlying breath sound; fine crackles (Audio 16-4) are softer, shorter in duration, and higher in pitch than coarse crackles (Audio 16-5). There is general agreement that the brief recurrent detonations that characterize fine crackles are caused by the explosive openings of small airways that had closed owing to the surface forces within them.^{79,84} This explains why fine crackles are much more common during inspiration than during expiration and why they are best heard over dependent lung regions—where airways are more likely to close—than over uppermost regions. This is also compatible with the presence of crackles in healthy elderly persons in whom dependent airways close at resting lung volumes. Crackles therefore are best heard during the first deep breaths at the lung bases posteriorly. After several such breaths or intentional coughing, these fine crackles will disappear if the small airways remain open throughout the time the patient is being examined.⁸⁴

The timing of crackles is also important. Nath and Capel⁸⁵ have shown that late-inspiratory crackles are more often found in restrictive than obstructive lung disease. In a study by Pürilä and colleagues,⁸⁶ the crackles of pulmonary fibrosis began at 45% of inspiration, whereas those of nonfibrotic lung conditions were heard earlier: COPD at 25%, bronchiectasis at 33%, and heart failure at 37% of inspiration.⁸⁶ This suggests that more tension is required to open individual airways in fibrosis than in lungs with secretions or edema. As inspiration progresses, radial traction on airway walls increase until suddenly they pop open.⁸⁵ Thus crackles heard later in inspiratory time imply that the tension required to open individual airways is greater. Coughing or deep inspiration may change the quality of coarse crackles, such as those associated with underlying alveolar or airway disease, but the crackles rarely disappear entirely. Expiratory crackles are much less frequent than inspiratory crackles and are often seen in obstructive lung disease.⁸³

Continuous Sounds (Wheezes)

The American Thoracic Society Committee on Pulmonary Nomenclature defined wheezing as high-pitched (dominant frequency of > 400 Hz) continuous adventitious lung

sounds.⁸² Continuous sounds are longer than 250 msec in duration. Wheezes are usually louder than the underlying breath sounds and frequently noted by patients. A leading theory is that wheezes are produced by fluttering of the airway walls and fluid together induced by a critical flow velocity.⁸⁷ The pitch of the wheeze is dependent on the mass and elasticity of the airway walls and the flow velocity. The degree of bronchial obstruction is proportional to the amount of the respiratory cycle that it occupies. There is no relationship to the intensity or pitch of the wheeze and pulmonary function. Wheezes are well heard over the trachea, and listening over the trachea may be superior to listening over the lung in most asthmatic patients⁸⁷ (Audio 16-6). Wheezing with forced expiration can sometimes be provoked in healthy subjects⁷⁹ and does not establish a diagnosis of asthma. More helpful is to elicit wheezing and/or coughing at a full expiration without forced effort. Because several disease states are associated with wheezing, additional information should be obtained to make the correct diagnosis.

Rhonchi are low-pitched continuous sounds with a dominant frequency of approximately 200 Hz or less (Audio 16-7). These sounds are likely to originate from rupture of fluid films and airway wall vibrations.⁷⁹ Rhonchi may clear with cough or with suctioning in intubated patients. Some have questioned whether the term rhonchi is needed at all, finding the substitute “low-pitched wheezes” more parsimonious.⁸⁸ However, the term retains its place in classification systems and in clinical usage.^{79,80,89}

Voice-Generated Sounds

Another way of generating sounds for auscultation is to have a patient speak while the examiner listens to his or her chest. Ordinarily the patient is asked to say in a quiet voice “one, two, one, two,” “ninety-nine, ninety-nine,” or “E, E.” If enhanced responses are heard, the patient repeats the words while whispering. Because sounds of central origin are attenuated as they are transmitted peripherally through normal air-filled lung, voice-generated sounds have a muffled quality and the words are indistinct. In contrast, in the presence of consolidation, the characteristics of the sounds are remarkably different. The term *egophony* (Audio 16-8) indicates sounds that have a high-pitched, bleating quality; a change in sound-filtering properties of consolidated lungs accounts for the presence of egophony, which does not require, as often stated, the presence of an overlying pleural effusion. *Bronchophony* (Audio 16-9) and *pectoriloquy* (Audio 16-10) both mean that spoken sounds are transmitted with increased intensity and pitch; when each syllable of every word, especially when whispered, is distinct and easily recognized, pectoriloquy is the preferred description. An E-to-A sign means that the spoken letter “E” sounds like “A” while listened to over the lungs. Each of these auscultatory findings is a manifestation of the same acoustic property of consolidated lungs and thus has similar diagnostic significance.

Pleural Friction Rub

The small amount of liquid normally present in the pleural space separates the visceral and the parietal pleural layers and allows the lungs to expand and contract freely during breathing. In contrast, when the pleural surfaces are

thickened and roughened by an inflammatory or neoplastic process, easy motion is prevented and a pleural friction rub may be produced. These sounds vary in intensity but often have a leathery or creaking quality that may be exaggerated by pressure with the stethoscope (Audio 16-11). Typically rubs are heard during both inspiration and expiration, but they are evanescent and variable and may be heard in only one part of the respiratory cycle. Surprisingly, rubs may still be heard in the presence of a large pleural effusion, which prevents the coarsened pleural surfaces from actually rubbing against each other.

Extrapulmonary Sounds

The presence of air or other gas in the mediastinum may be associated with crunching, crackling sounds that are synchronous with cardiac contraction and are audible when breathing is momentarily stopped. The finding of a mediastinal crunch by auscultation usually signifies mediastinal emphysema, even when the chest radiograph shows no abnormalities. In contrast, a pleural friction rub is usually heard during both inspiration and expiration and has a higher pitch.

Stridor is a high-pitched continuous sound produced by turbulent flow in the extrathoracic airway, which—in contrast to wheezing—is louder and longer during inspiration than expiration (Audio 16-12). Stridor has many causes,⁹⁰ some of which are life-threatening and need immediate attention (see Chapter 49).

As previously mentioned, various sounds may originate from the chest wall itself. Some of these have pathologic significance; others do not. Rubbing hairs trapped between the skin and the stethoscope produce intermittent crackling sounds that may be confused with crackles (Audio 16-13). Variable crackles are also produced when the stethoscope is placed over an area of subcutaneous emphysema and is rocked back and forth (Audio 16-14). Contracting chest wall muscles may generate sounds that have a muffled, distant, low-pitched, and rumbling quality. Occasionally it is possible to hear a snapping sound during breathing from motion of a newly fractured rib (Audio 16-15).

Interpretation

When abnormalities are discovered on physical examination of the chest, it is useful to identify them by their anatomic location in the involved lung. This requires knowledge of the surface projections of the underlying bronchopulmonary lobes, which are shown in Figure 16-2. The upper and lower lobes of both lungs are separated by the two oblique fissures, which course from the spinous process of the third thoracic vertebra posteriorly to the level of the 6th rib in the midclavicular line anteriorly. On the right side anteriorly, the upper and middle lobes are separated by the horizontal fissure, which lies at about the level of the fourth costal cartilage. In the presence of either distortions of pulmonary anatomy or the shape of the rib cage, the surface projections of the underlying lung also change.

The classic findings on physical examination of the chest in some common pulmonary disorders are shown in Table 16-3. Ordinarily, consolidation must be within 1 or 2 cm of the costal surface to be reliably detected. Even then, physical examination alone cannot be relied upon to diagnose or exclude pneumonia.⁹¹ Some pneumonias,

Table 16-3 Classic Physical Findings in Some Common Pulmonary Disorders

Disorder	Inspection	Palpation	Percussion	Auscultation
Bronchial asthma (acute attack)	Hyperinflation; use of accessory muscles	Impaired expansion; decreased fremitus	Hyperresonance; low diaphragm	Prolonged expiration; inspiratory and expiratory wheezes
Pneumothorax (complete)	Lag on affected side	Absent fremitus	Hyperresonant or tympanitic	Absent breath sounds
Pleural effusion (large)	Lag on affected side	Decreased fremitus; trachea and heart shifted away from affected side	Dullness or flatness	Absent breath sounds
Atelectasis (lobar obstruction)	Lag on affected side	Decreased fremitus; trachea and heart shifted toward affected side	Dullness or flatness	Absent breath sounds
Consolidation (pneumonia)	Possible lag or splinting	Increased fremitus on affected side	Dullness	Bronchial breath sounds; bronchophony; pectoriloquy; crackles

Modified from Hinshaw HC, Murray JF, editors: *Diseases of the chest*, ed 4, Philadelphia, 1980, WB Saunders, p 23.

Figure 16-2 Schematic drawing shows surface projections of underlying lobar anatomy of a healthy man. Ling, lingular division of left upper lobe; LLL, left lower lobe; LUL, left upper lobe; RLL, right lower lobe; RML, right middle lobe; RUL, right upper lobe.

such as *Mycoplasma pneumoniae*, typically cause surprisingly few physical abnormalities despite extensive radiographic involvement (see eFig. 33-9) but, even in patients with classic lobar pneumonia, the findings may be nonspecific. Although unable to distinguish reliably between new-onset pneumonia and other pulmonary diseases, the findings from physical examination—vital signs, mental

confusion, cyanosis, use of accessory muscles, and paradoxical breathing—are extremely important in assessing severity and in deciding whether or not to hospitalize patients with pneumonia.⁹²

The distinction between pleural effusion and atelectasis can be made on physical examination by determining whether the heart and mediastinal contents shift toward or away from the abnormal side, a finding that can usually be made only if the effusion is large or the atelectasis involves at least one lobe. When these full-blown manifestations are present, the presence of the causative disorder can be inferred with reasonable certainty. However, the absence of these findings does not exclude an abnormality, and a chest radiograph must always be taken as part of the complete pulmonary workup.

EXTRAPULMONARY MANIFESTATIONS

The examination of the lungs and pleura unlock only some of the clues to the presence of lung disease. Looking for extrapulmonary signs can often point toward a specific pulmonary disease or toward systemic diseases such as lupus erythematosus or toward diseases arising elsewhere in the body that secondarily involve the lung. Certain extrapulmonary manifestations are particularly useful.

Clubbing

The association of clubbing of the fingers or toes with disease has caught the attention of physicians since the time of Hippocrates. Clubbing is easy to recognize when it is severe (Fig. 16-3), but subtle changes are more common and less reliable. The hallmarks of clubbing are (1) a softening and periungual erythema of the nail beds, which causes the nails to seem to float rather than to be firmly attached, (2) an increase of the normal 165-degree angle that the nail makes with its cuticle, (3) an enlargement or bulging of the distal phalanx, which may be warm and erythematous, and (4) a curvature of the nails themselves. Of these features, the straightening of the nail cuticle angle appears to be the most sensitive measurement.⁹³

Patients with clubbing may also have *hypertrophic osteoarthropathy*, a condition characterized by subperiosteal formation of new cancellous bone at the distal ends of

Figure 16-3 Clubbing of the digits as seen in severe diffuse interstitial pulmonary fibrosis. (From Cashman MW, Sloan SB: Nutrition and nail disease. *Clin Dermatol* 28: 420–425, 2010, Figure 2.)

Figure 16-4 Radiographs of the leg show marked subperiosteal new bone formation (arrows) that is diagnostic of hypertrophic osteoarthropathy. A, Most of tibia and fibula. B, Detailed view near the ankle.

long bones, especially the radius and ulna and the tibia and fibula. Hypertrophic osteoarthropathy (Fig. 16-4) is almost always associated with clubbing, particularly in patients with bronchogenic carcinoma, other intrathoracic malignancies, and cystic fibrosis. It occasionally develops in patients with bronchiectasis, empyema, and lung abscess but is rare in patients with most of the other

conditions in which clubbing has been observed.⁹⁴ One of the striking features of clubbing is the speed with which it can develop, about 2 weeks in patients with new-onset empyema, and with which it can reverse, also about 2 weeks in patients after corrective cardiac surgery. The presence of clubbing, which was found in 1% of all admissions to an internal medicine department, was associated with “serious disease” in 40% of afflicted patients⁹⁵; therefore new-onset clubbing always warrants a chest radiograph, and if no abnormality is found, a CT scan to look for a pulmonary neoplasm or other lesion, which may still be localized and curable.

Clubbing has been found in many diverse conditions, such as children with HIV,⁹⁶ hepatopulmonary syndrome,⁹⁷ and benign asbestos pleural disease⁹⁸ (Table 16-4). Both clubbing and hypertrophic osteoarthropathy can be idiopathic or familial; the familial form is often transmitted as a dominant trait. The hereditary form of hypertrophic osteoarthropathy is also called *pachydermoperiostosis*, a condition in which bone and joint involvement is often mild but furrowing of the skin of the face and scalp is usually marked.

The main pathologic finding in clubbing is increased capillary density. The most potent stimulus to new capillary growth is hypoxia, which causes an intense production of vascular growth factors, such as vascular endothelial growth factor. With histochemical staining, Atkinson and Fox⁹⁹ showed increases in vascular endothelial growth factor, platelet-derived growth factor, hypoxia-inducible factor-1 α , and hypoxia-inducible factor-2 α along with increased microvessel density in the stroma of clubbed digits. The second common characteristic of patients with digital clubbing is shunting of blood past the capillary bed of either the lung or the liver, which suggests that lack of metabolism of angiogenic factors that bypass a critical organ may be involved. Several of the conditions associated with clubbing have inflammation and shunting, such as bronchiectasis and liver cirrhosis.

Other Extrapulmonary Associations

Besides clubbing, thoracic neoplasms may cause other extrathoracic abnormalities that may become evident on physical examination, including anemia, Cushing syndrome, gynecomastia, and other paraneoplastic syndromes (Table 16-5). Other common extrathoracic manifestations that provide clues to the presence or state of an underlying malignancy are wasting, hoarseness, adenopathy (especially supraclavicular), and hepatomegaly. When evaluating patients with dyspnea, a thorough examination of the neck veins for evidence of increased central venous pressure and careful cardiac auscultation for the presence of a third heart sound or distinctive murmurs should be performed to exclude heart failure.¹⁰⁰ The extremities should also be examined for evidence of peripheral edema, venous thrombosis, chronic venous stasis, and scars that suggest injection drug abuse.

The association of abnormalities in other organ systems with underlying lung disease can be very helpful in making a diagnosis.

Important lesions associated with various primary lung disorders are listed in tables available in the electronic version of the text at ExpertConsult.

A wide variety of cutaneous or subcutaneous lesions (eTable 16-1)⁹⁹ and ocular lesions (eTable 16-2)¹⁰⁰ has been associated with various primary lung disorders. Likewise, a combination of lung and kidney disease (eTable 16-3); lung

and bone, joint, muscle, or nerve lesions (eTable 16-4); and gastrointestinal and hepatic involvement (eTable 16-5) may suggest a unifying disease process that can be detected by physical examination.

Table 16-1 Skin and Subcutaneous Lesions Associated with Lung Disease**SKIN LESIONS**

Diffuse pigment change
Acanthosis nigricans—lung neoplasm
Albinism—Hermansky-Pudlak syndrome
Bronze pigmentation—hemosiderosis
Gray-brown—Whipple disease
Cutaneous draining sinus
Fungal infections (especially histoplasmosis)
Mycobacterial infections (especially tuberculosis)
Necrotizing vasculitis
Neoplasms (especially mesothelial tumors)
Other bacterial infections (especially actinomycosis)
Cutaneous ulcers
Beryllium disease
Chronic venous insufficiency
Fungal infections (especially histoplasmosis)
Mycobacterial disease
Necrotizing vasculitis
Parasitic disease
Polycythemia
Sickle cell disease
Tularemia
Cutaneous vasculitis
Behçet syndrome
Collagen vascular disease
Eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome)
Granulomatosis with polyangiitis (Wegener granulomatosis)
Sarcoidosis
Erythema multiforme
Drug reactions
Fungi (especially coccidiomycosis)
Mycoplasma and other infectious agents
Neoplasms
Exfoliative dermatitis
Adverse drug reactions
Chemotherapy
Disseminated malignancy
Graft-versus-host disease
Radiation therapy
Flushing
Bronchial carcinoid, pheochromocytoma, other neoplasms
Carbon dioxide, cyanide, and other toxins
Drugs
Foods and vasodilatory substances
Hormones
Mastocytosis
Metabolic states (e.g., hyperthyroidism, fever)
Macular rash
Anti-glomerular basement membrane disease
Café-au-lait spots (neurofibromatosis)
Coal miner's scars
Collagen vascular disease
Idiopathic pulmonary fibrosis
Rose spots (psittacosis)
Sarcoidosis
Syphilis
Viral pneumonia
Maculopapular rash
Amyloidosis
Drug-induced lung disease
Collagen vascular disease
Gaucher disease
Kaposi sarcoma
Lung neoplasm
Lymphoma
Lymphomatoid granulomatosis
Parasites
Sarcoidosis
Syphilis
Vasculitis
Viral pneumonia
Sicca syndrome (dry mouth and eyes)
Gaucher disease
Lymphocytic interstitial pneumonia
Sjögren syndrome
Telangiectasia
Arteriovenous malformation
Ataxia-telangiectasia
Carcinoid syndrome
Cushing disease
Hepatopulmonary syndrome and other chronic liver diseases
Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu)
Mastocytosis
Systemic sclerosis and other collagen vascular diseases

Urticaria
Asthma
Drug reactions
Cystic fibrosis
Exercise-induced urticaria
Food allergy
Hereditary angioneurotic edema
Infectious agents, such as *Mycoplasma* and *Helicobacter*
Inhaled antigens
Insect bites and stings
Mastocytosis
Occupational sensitization
Parasites
Vasculitis

NAIL CHANGES WITH LUNG DISEASE

Color changes
Cigarette smoking discoloration
Splinter hemorrhages
Yellow nail syndrome
Beau lines (any severe illness)
Dermatomyositis
Sarcoidosis
Seronegative arthropathies
Systemic sclerosis

LUNG DISEASE WITH SUBCUTANEOUS INVOLVEMENT

Adenopathy
Environmental mycobacteria
Fungal infections
HIV infections
Metastatic neoplasm
Leukemia
Lymphoma
Sarcoidosis
Tuberculosis
Calcinosis
Dermatomyositis
Metastatic osteosarcoma
Mixed connective tissue disease
Scleroderma
Tuberculosis
Uremic metastatic calcification
Erythema induratum (Bazin disease)
Aortic stenosis
Cryoglobulinemia
Nodular vasculitis
Panniculitis
Peripheral neuropathy
Streptococcus infection
Takayasu disease
Tuberculosis and other mycobacterial disease
Weber-Christian disease
Erythema nodosa
Neoplasm
Other infectious and inflammatory diseases
Primary coccidiomycosis, histoplasmosis
Primary tuberculosis
Psittacosis
Sarcoidosis
Subcutaneous nodules
Amyloidosis
Neoplasm
Neurofibromatosis
Rheumatoid arthritis
Tuberous sclerosis (angiofibromas)
von Recklinghausen disease
Weber-Christian disease

LUNG DISEASE WITH SALIVARY GLAND ENLARGEMENT

Bulimia and aspiration
Gaucher disease
Lymphatic carcinoma
Lymphoid interstitial pneumonitis
Lymphoma
Other causes of lymphadenopathy
Sarcoidosis
Sjögren disease

eTable 16-2 Eye Involvement in Lung Disease

BLINDNESS Amaurosis fugax Antiphospholipid syndrome Aspergillosis Eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome) Granulomatosis with polyangiitis (Wegener granulomatosis) Temporal arteritis Giant cell arteritis Late stage of many diseases Sarcoidosis	RETINA Antiphospholipid syndrome Behçet disease Candidiasis Cytomegalovirus, herpes, and other viruses Diabetes Disseminated intravascular coagulation Dysproteinemia Ehlers-Danlos syndrome Embolic disease Endocarditis Fat emboli Fungemia Genetic metabolic deficiencies Granulomatosis with polyangiitis HIV disease Leukemia, lymphoma Lupus erythematosus Macroglobulinemia Marfan syndrome Neoplasm (especially melanoma) Polycythemia Sarcoidosis Sickle cell disease Subacute bacterial endocarditis, sepsis (Roth spots) Syphilis Temporal arteritis Toxoplasmosis Trauma Tuberous sclerosis
CHOROID Histoplasmosis Lupus erythematosus Toxoplasmosis	
CONJUNCTIVA Allergic reaction Chlamydia Granulomatosis with polyangiitis Herpes Kaposi sarcoma Sarcoidosis	
CORNEA Chlamydia Granulomatosis with polyangiitis Herpes Syphilis	
IRIS Neoplasm Neurofibromatosis	
LENS Cataracts Steroid use Tobacco smoking Marfan syndrome (dislocated)	SCLERA AND EPISCLERA Granulomatosis with polyangiitis Inflammatory bowel disease Rheumatoid arthritis Sarcoidosis Scleroderma Systemic lupus Systemic vasculitis
LIDS Proptosis Graves disease Leukemia Neoplasm Ptosis Myasthenia gravis Muscular dystrophy	SICCA Graft-versus-host disease Rheumatoid arthritis Sjögren syndrome
OPTIC NERVE Cryptococcosis Granulomatosis with polyangiitis Graves disease Leukemia Neurofibromatosis Sarcoidosis Syphilis	UVEA Ankylosing spondylitis Behçet disease Crohn disease Granulomatosis with polyangiitis Herpes zoster Inflammatory bowel disease Reactive arthritis Rheumatoid arthritis Sarcoidosis Syphilis

eTable 16-3 Renal Involvement in Lung Disease**GLOMERULONEPHRITIS**

Anti-glomerular basement membrane disease
Sarcoidosis
Collagen vascular disease
Systemic vasculitis

NEPHROTIC SYNDROME

Amyloidosis
Disseminated Langerhans cell histiocytosis
Drug-induced lung disease
Paraneoplastic syndrome
Post transplantation
Pulmonary hydatid disease
Systemic lupus erythematosus
Vasculitis
Venous thrombosis

RENAL MASS

Granulomatosis with polyangiitis (Wegener's granulomatosis)
Lymphangioleiomyomatosis
Metastatic neoplasm
Renal carcinoid
Tuberous sclerosis

NEPHROLITHIASIS

Alveolar proteinosis
Cystic fibrosis
Hypercalcemic syndromes
Osteolysis from mycobacteria or fungi
Sarcoidosis

SYSTEMIC HYPERTENSION

Collagen vascular disease
Diffuse alveolar hemorrhage
Neurofibromatosis
Pulmonary-renal syndromes
Sleep apnea

eTable 16-4 Joint, Bone, Muscle, and Neurologic Involvement in Lung Disease**ARTHRITIS**

Ankylosing spondylitis
Collagen vascular diseases
Reactive arthritis
Sarcoidosis
Systemic vasculitis
Tuberculosis

BONE LESIONS

Ankylosing spondylitis
Blastomycosis and other fungal disease
Collagen vascular diseases
Eosinophilic granulomatosis
Fibrous histiocytoma
Gaucher disease
Neoplasm
Sarcoidosis
Tuberculosis

MUSCLE DISEASE

Collagen vascular disease
Diabetes insipidus
Eosinophilic granulomatosis
L-Tryptophan
Polymyositis
Sarcoidosis

NEUROLOGIC DISEASE

Acute inflammatory polyneuropathy
Amyotrophic lateral sclerosis
Aspiration
Botulism
Eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome)
Granulomatosis with polyangiitis (Wegener granulomatosis)
Lambert-Eaton syndrome
Myasthenia gravis
Organophosphate poisoning
Polio and postpolio syndrome
Sarcoidosis

eTable 16-5 Gastrointestinal and Hepatic Involvement in Lung Disease**ESOPHAGEAL REFLUX**

Aspiration pneumonia
 Asthma
 Bronchiectasis
 Bronchitis
 Cough
 Mycobacterial disease
 Pulmonary fibrosis
 Scleroderma

INFLAMMATORY BOWEL DISEASE

Adverse reactions to drug treatments
 Bronchiectasis
 Bronchiolitis
 Bronchitis

COLOBRONCHIAL FISTULA

Desquamative interstitial lung disease
 Eosinophilic lung disease
 Interstitial lung disease
 Necrobiotic nodules
 Obstructive lung disease
 Organizing pneumonia
 Sarcoidosis
 Serositis affecting pleura or pericarditis
 Tracheal stenosis

LIVER

Alpha₁-antitrypsin deficiency
 Chronic active hepatitis
 Hepatopulmonary syndrome
 Portopulmonary hypertension
 Primary biliary cirrhosis
 Hepatosplenomegaly
 Amyloidosis
 Collagen vascular disease
 Eosinophilic granulomatosis
 Lymphatic interstitial pneumonia
 Sarcoidosis

Table 16-4 Causes of Clubbing (Partial Listing)

NOT ASSOCIATED WITH OVERT DISEASE Hereditary clubbing Sporadic clubbing Pachydermoperiostosis	GASTROINTESTINAL AND LIVER DISEASE Inflammatory bowel disease Crohn disease Ulcerative colitis Polyposis coli Amebic colitis Bacillary dysentery Liver disease Hepatoma Hepatopulmonary syndrome Biliary cirrhosis Esophageal stricture
THORACIC NEOPLASMS Lung cancer especially fibrous tumors (accounts for most clubbing) Benign and malignant pleural tumors Other thoracic neoplasms, including esophageal cancer, and lymphoma	HEMOGLOBINOPATHY Hemoglobinopathies Congenital methemoglobinemia
HEART AND VASCULAR DISEASE Cyanotic congenital heart disease Subacute bacterial endocarditis Infected aortic graft Aortic surgery Takayasu arteritis Behçet syndrome	OTHER Thyroid acropathy Secondary hyperparathyroidism HIV-related Lymphoid interstitial pneumonia Other infections Prostaglandin infusion Fabry disease Toxic exposure to arsenic, mercury, or beryllium
PULMONARY AV SHUNTING Cyanotic congenital heart disease Acquired heart disease Pulmonary AV fistula Hereditary hemorrhagic telangiectasias	UNILATERAL CLUBBING Vascular disorders Subclavian artery aneurysm Brachial AV fistula Subluxation of the shoulder Median nerve injury Local trauma Hemiplegia
INTERSTITIAL LUNG DISEASE Asbestosis Idiopathic pulmonary fibrosis Collagen vascular disease Langerhans cell histiocytosis Lipoid pneumonia	
CHRONIC INFECTIONS Bronchiectasis Bronchiectasis from sarcoidosis or tuberculosis Lung abscess Empyema Cystic fibrosis	

AV, arteriovenous.

Table 16-5 Paraneoplastic Syndromes (Partial Listing)

PARANEOPLASTIC SYNDROMES Acanthosis nigricans Clubbing Hypertrophic osteoarthropathy Intravascular thrombosis Muscle weakness	Neuropathy Pemphigoid Polymyositis-dermatomyositis Raynaud phenomenon
ENDOCRINE SYNDROMES ASSOCIATED WITH LUNG NEOPLASMS Acromegaly (growth hormone) Diarrhea (vasoactive intestinal peptide) Hypercalcemia (parathyroid-like substance) Hyponatremia (inappropriate antidiuretic hormone) Carcinoid syndrome (serotonin)	Cushing syndrome (ACTH) Gynecomastia (gonadotropins) (prolactin) Hyperglycemia and hypoglycemia (insulin) Skin pigmentation (melanocyte-stimulating hormone, ACTH)

ACTH, adrenocorticotropic hormone.

Key Points

- Taking a careful history and performing a thorough physical examination are essential first steps in formulating a preliminary differential diagnosis of a patient's complaints.
- After the clinician arrives at a tentative diagnosis, selected radiographic, laboratory, and other tests are ordered for further and confirmatory evaluation.
- The electronic medical record provides documents of higher quality than written records, owing to improved organization, increased readability, use of supplementary material, and better comparisons.
- Because dyspnea, cough with or without hemoptysis, and chest pain are among the most common reasons for patients to visit physicians and because these symptoms may result from serious underlying chest disease, careful questioning and workup is mandatory.
- Physical examination can be performed virtually anywhere, provides important information, lends itself to serial observations, and increases patients' confidence in their physicians.
- Stridor, a high-pitched continuous sound which, in contrast to wheezing, is louder and longer during inspiration than expiration, can indicate a life-threatening upper airway obstruction and requires immediate attention.
- New-onset clubbing of the digits warrants detection and investigation owing to its frequent association with serious underlying disease.

INTRODUCTION

The clinical microbiology laboratory plays a critical role in diagnosis and management of patients with lower respiratory tract infections. By providing pathogen detection and identification and susceptibility testing the laboratory provides the basis of optimal empirical antimicrobial therapy and individually tailored regimens.¹ The microbiology laboratory also provides epidemiologic data that assist the hospital epidemiologist in the prevention, detection, investigation, and termination of nosocomial outbreaks.² When correctly and promptly used, the information provided by the clinical microbiology laboratory improves clinical outcomes, reduces unnecessary utilization of antibiotics, and prevents nosocomial transmissions.^{3,4}

The primary aim of this chapter is to assist clinicians in efficient and effective utilization of the resources of the clinical microbiology laboratory in diagnosis of the causes of infections of the lower respiratory tract. This chapter assumes that clinical laboratories are using validated methods and reporting quality-assured results and does not delve into technical or operational aspects of the clinical microbiology laboratory. For additional information on laboratory operation, the reader is referred to the latest edition of the *Manual of Clinical Microbiology* (American Society for Microbiology).⁵

PREANALYTIC PRINCIPLES

PRINCIPLES OF TESTING

The decision to order a diagnostic test should hinge on whether the result is likely to affect the clinician's treatment decisions. If the clinician is certain the patient has a disease based on clinical presentation and prevalence (high pretest probability), then the decision to treat will likely not be altered by the test result and testing should not be ordered. Similarly, testing should not be ordered if the clinician has a high degree of a priori certainty that the patient does not have a disease, because the decision not to treat will likely not be altered by the test result. Testing is most useful when the clinician is uncertain about the probability of disease and the result can sway the physician's decision about

treatment. In addition to the pretest probability, several factors affect this decision. For example, if therapy comes at a low harm (in terms of toxicity, dollar cost, and selection of resistance), then treating all patients without testing may be appropriate. If the diagnostic has a low sensitivity (i.e., the test is positive in a low percentage of patients with disease), then testing may lead to an inappropriate decision not to treat. Similarly, if a diagnostic has a low specificity (i.e., the test is positive in a high percentage of patients without disease), then testing may lead to unnecessary treatment. The determination that clinical suspicion is uncertain enough to benefit from a particular diagnostic involves the interplay of the cost and accuracy of the diagnostic test, the pretest probability of the disease, and the benefit and harm of treatment.

INFECTION PREVENTION

The clinician plays a critical role in notifying the microbiology laboratory (and the hospital infection control epidemiologist) when virulent and transmissible agents are suspected as the cause of disease. Alerting laboratory staff reduces the exposure risk of laboratory staff handling specimens and cultures harboring highly virulent pathogens. A list of such pathogens is shown [Table 17-1](#). Not all specimens from patients with infectious diseases should be handled by the on-site laboratory. According to guidelines developed by local and national public health officials, specimens potentially containing selected high-risk agents such as *Bacillus anthracis* spores, *Francisella tularensis*, *Yersinia pestis*, variola major, hemorrhagic fever viruses, or *Clostridium botulinum* toxin are directly sent to the public health laboratories, where appropriate containment facilities and diagnostic tools are applied to make a diagnosis. Other pathogens that are handled by the on-site laboratory but still require laboratory notification include *Coccidioides* and *Brucella* species, because cultures of these are associated with a high risk for laboratory-associated infection. Although the technologists are expected to handle all specimens and microbiologic cultures using universal precautions, accidental exposures can happen, especially if the findings are unexpected. Therefore laboratory notification serves to alert the staff to protect themselves from potential exposure to highly transmissible agents.

SYNDROMIC ORDER SETS

The diversity of etiologic agents of lower respiratory tract infection poses a number of diagnostic challenges to the clinician. First the provider must formulate a comprehensive yet pragmatic differential diagnosis that takes into account the clinical presentation, immune status, and the exposure history of the patient. Then the clinician must order the correct set of laboratory tests and ensure collection of the appropriate specimens and their placement in correct transport containers as well as their transport to the laboratory under permissive conditions for testing. Because improper test selection and specimen collection could reduce the analytic sensitivity and specificity of assays performed in the laboratory, syndromic order sets have been designed that consider the most common pathogens for the specific syndrome. Syndromic order sets incorporate general guidelines for the types of specimen required, collection and transport, and available assays for pathogens expected in a given clinical setting or syndrome. By prioritizing diagnostics that maximize yield and avoiding the need to repeat invasive procedures, these order sets also serve to minimize risk to the patient and to lower health care costs. However, it is the responsibility of the clinician to ensure that specimen requirements are met and the most critical tests are prioritized, especially when the amount of specimen material obtained is limited and multiple tests are ordered. [Tables 17-2, 17-3, and 17-4](#) show syndromic order sets for *community-acquired pneumonia* (CAP), *hospital-acquired and ventilator-associated pneumonia*, and *immunocompromised host pneumonia*, respectively. Order sets developed to address local epidemiologic characteristics and preanalytic practices may be tailored to serve each institution. Clinicians also should familiarize themselves with

local sample storage practices in case additional tests need to be performed.

SPECIMEN SELECTION, COLLECTION, AND TRANSPORT

In general, sterile specimens such as tissue samples and aspirates are the most valuable diagnostically because the absence of contamination with commensal organisms ensures that any organism detected likely represents a true pathogen. Histopathologic examination of tissue also provides information on the immunopathologic characteristics of the infectious process. However, a major diagnostic challenge of lower respiratory tract infection is that lower respiratory tract secretions are usually obtained through the oropharynx, which normally contains 10^{10} to 10^{12} *colony-forming units* (CFU) of aerobic and anaerobic bacteria per milliliter. Therefore lower respiratory tract secretions collected for microbiologic examination are commonly contaminated with diverse bacteria ([Table 17-5](#)),⁶ some of which, such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, and *Neisseria meningitidis*, can also be pathogens of the lower respiratory tract.⁷⁻⁹ The oropharynx can also contain *Mycoplasma pneumoniae*¹⁰ and aerobic actinomycetes including *Nocardia* and nontuberculous mycobacteria in the absence of disease.¹¹ In addition, aspiration of even minute amounts (0.1 to 1 μ L) of oropharyngeal secretions can deliver a bolus of 10^9 CFU to the tracheobronchial tree. The distinction in such cases between colonization of the upper respiratory tract and pneumonia cannot be easily made by sputum examination and culture. Another challenge is that oropharyngeal secretions, which normally contain only a few gram-negative bacilli (such as Enterobacteriaceae, *Pseudomonas*, *Acinetobacter*), often become colonized with as many as 10^7 CFU of gram-negative bacilli per milliliter in seriously ill patients requiring intensive care,¹² patients treated with antibiotics after hospitalization for acute pulmonary inflammatory disease,¹³ chronic alcoholic and diabetic patients,¹⁴ institutionalized older adults and chronically ill patients,¹⁵ and hospitalized patients with acute leukemia.¹⁶ Lastly, *Aspergillus* spores present in the environment are commonly deposited in the lower respiratory tract and may be recovered from sputum in the absence of disease, although in immunocompromised patients it is best to consider this finding seriously.¹⁷ In summary, because lower respiratory tract secretions collected through the oropharynx are nearly always contaminated with resident microflora of the oral cavity and

definitive diagnosis would require sterile lung tissue with demonstration of parenchymal invasion, appropriate steps must be taken to obtain specimens of highest quality for microbiologic testing.

Expectorated sputum is the specimen most frequently obtained for the laboratory diagnosis of lower respiratory tract infection.⁵ The importance of proper sputum collection was documented by Laird¹⁸ 100 years ago in studies on

the yield of *Mycobacterium tuberculosis* according to the appearance and cellular composition of the sputum examined. The first requirement for collection of a good-quality sputum specimen is an alert and cooperative patient who can be instructed to rinse out his or her mouth with water or even brush his or her teeth before producing a lower respiratory tract specimen. The patient then must be encouraged to cough deeply to expectorate a specimen of lower respiratory tract secretions. With some infections such as *tuberculosis* (TB), a larger sample volume can improve the sensitivity of culture.¹⁹ Specimens are to be collected in sterile, leakproof, screw-capped containers. Containers should be transported in a watertight plastic biohazard bag.

Although a single sputum specimen may be sufficient for establishing the diagnosis of an acute bacterial process, collection of a series of two or three sputum specimens obtained on one or two days is recommended for patients suspected of having mycobacterial infections.²⁰ In patients with non-productive cough or suspected mycobacterial, fungal, or *Pneumocystis jirovecii* infections,²¹ it may be helpful to

induce sputum production with an inhaled aerosol of hypertonic salt solution (3% to 10%).

Once collected, the specimens should be rapidly delivered to the laboratory for processing to avoid overgrowth by contaminating flora, which can compromise microscopic detection and isolation of pathogenic bacteria.^{22,23} Penn and Silberman²³ found that organisms observed microscopically on Gram-stained smears of sputum specimens and their relative numbers in cultures changed dramatically between processing within an hour of collection and processing after overnight refrigeration. Although there were no significant differences in the culture results between the immediate and delayed cultures in this study, the loss of reliable microscopic features had significant impact on the interpretation of culture results. Processing delay is particularly important for culture recovery of slow-growing mycobacteria.²⁴ Specimens that are not sent to the laboratory for processing within 2 hours should be refrigerated for no more than 5 days. If refrigeration is not possible, samples should be treated first with equal volume of 0.6% cetylpyridinium bromide or 1% cetylpyridinium chloride in 2% sodium chloride, which reduces the survival of contaminating microorganisms while preserving the viability of *M. tuberculosis* for up to 8 days.²⁴⁻²⁶ Although the recovery of fungi is optimal from cultures of fresh specimens, most clinically significant fungi appear to survive storage of 16 days or longer.²⁷ Specimens for viral cultures should be shipped refrigerated but not frozen, whereas specimens for chlamydial culture should be placed into sucrose phosphate medium and shipped frozen.

Although there is no universal agreement on the value of anaerobic culture,²⁸ protected catheter brushes may be used to obtain samples for culture and identification of organisms causing anaerobic pleuropulmonary disease.²⁹ It is essential to transport samples in an anaerobic vial to preserve the viability of anaerobic organisms.

For detection of respiratory viruses, nasopharyngeal specimens are preferred, although lower respiratory tract specimens may be necessary to detect viral infection of the lower respiratory tract.³⁰ There are a number of methods for the collection of nasopharyngeal specimens, which includes flocked and traditional swabs, as well as aspirates and washes. Flocked swabs contain perpendicular arrangements of fibers with an open structure to create a highly absorbent thin layer capable of efficient uptake of respiratory samples and elution into viral transport media. Nasopharyngeal flocked swabs have been shown to be more sensitive for the detection of respiratory viruses than traditional swabs.^{31,32} In turn, nasopharyngeal aspirates or washes have been shown to be more sensitive than nasopharyngeal flocked swabs.³³⁻³⁵ However, the modest gains in sensitivity for detection of most respiratory viruses using aspirates or washes may be offset by the ease of nasopharyngeal specimen collection using flocked swabs. Oropharyngeal specimens are less sensitive than nasopharyngeal specimens, though the combination may increase respiratory virus detection.³⁶⁻³⁹ Oropharyngeal swabs may also be used for detecting *Chlamydia pneumoniae*,⁴⁰⁻⁴³ *M. pneumoniae*,^{40,44,45} and *Legionella* species.⁴⁰

In patients who are critically ill, immunocompromised, or who cannot produce expectorate, one or more invasive approaches may be necessary to obtain diagnostic samples.

Specimens may include endotracheal aspirates, pleural fluids, bronchoalveolar lavage (BAL), percutaneous lung aspirate, or lung biopsies.^{5,46} The use of BAL has also been expanded to include diagnosis of bacterial pneumonia, especially for nosocomial cases.⁴⁷⁻⁴⁹ In patients with CAP requiring admission to the hospital, use of protected catheter brush and BAL has been shown to provide microbiologic diagnoses that are not obtainable by noninvasive means,⁵⁰ although there is little support for using these procedures to diagnose CAP.⁵¹ Although the results of cultures from protected catheter brushes and BAL specimens are quantitatively similar, Meduri and Baselski⁵⁰ concluded that BAL specimens provided a larger and more representative sample of lower respiratory tract secretions than the protected catheter brushes, allowing microscopic analysis of the cytocentrifuged BAL fluid to identify the type of bacteria present and to demonstrate the presence of neutrophils with intracellular organisms. These procedures may also yield additional pathogens not obtainable by noninvasive approaches. Much work has also been done with the use of BAL for the diagnosis of ventilator-associated pneumonia,⁴⁹⁻⁵² (see Chapter 34).

In children under 7 years of age with suspected TB, gastric aspirate is used as a surrogate for respiratory samples. Historically it has been recommended that the pH of gastric aspirate be neutralized with sodium bicarbonate before transport to the laboratory; however, a recent study suggests that neutralization of gastric aspirate may reduce the recovery of *M. tuberculosis*.⁵³ Nasopharyngeal aspirates have also been used for diagnosis of TB, although the sensitivity of culture-confirmed TB is lower compared to induced sputum.⁵⁴ Stool samples in children with pulmonary TB may become the specimen of choice if processing methods can be optimized to concentrate the tubercle bacilli.^{55,56}

Other specimen types that may aid in diagnosis of lower respiratory tract infection include whole blood for blood culture, serum for antibody and antigen testing, and urine for antigen testing. Blood culture is recommended in cases of severe pneumonia⁵⁷ but is positive only up to 37% in CAP and in less than 25% in nosocomial pneumonia.⁵⁷⁻⁶¹ It is important to note that a large blood volume (60 mL or three sets of blood culture bottles in adults) is necessary to maximize sensitivity of blood culture.^{62,63} Although routine blood culture systems have been shown to be highly sensitive for detection of candidemia and cryptococemia, automated blood culture systems are insensitive for cultivation of monomorphic and dimorphic molds. Isolation of molds (and fastidious bacteria) from blood requires the lysis-centrifugation method (Isolator)⁶⁴⁻⁶⁶ or the use of enriched fungal medium bottles.^{67,68}

S. pneumoniae can be recovered from urine cultures in as many as 38% of patients with pneumococcal pneumonia.⁶⁹ Urine may be tested for the presence of pneumococcal⁷⁰ and *Legionella pneumophila* serogroup 1⁷¹ antigens. Fungal antigen tests of urine are also available for diagnosis of histoplasmosis and blastomycosis.^{72,73} Antigen assays are discussed later in this chapter.

SPECIMEN ADEQUACY

Clinical laboratories are mandated by accrediting agencies to monitor specimen quality and quantity, and to enforce

rejection criteria when sample requirements are not met. Common causes for rejection include insufficient sample quantity, poor sample quality, and mislabeling of samples. For bacterial cultures, microscopic examination of sputum and endotracheal aspirate with Gram stain is used to screen samples for adequate quality.^{18,74} The presence of excessive squamous epithelial cells (>10 to 25 per low-power field) is indicative of oropharyngeal contamination and therefore grounds for rejection for bacterial culture (Fig. 17-1). Although earlier criteria for the adequacy of sputum specimens for bacterial cultures also required the presence of polymorphonuclear leukocytes (neutrophils), the number of neutrophils in a sample is no longer used to evaluate specimen adequacy.⁷⁵ Endotracheal aspirates are rejected if the screening Gram-stained smears show no organisms.^{74,76} For mycobacterial, fungal, and viral cultures, cytologic screening to determine specimen

acceptability is not enforced, because contamination with commensals does not interfere with interpretation of the culture results. However, the presence of respiratory columnar epithelial cells has been shown to improve respiratory virus detection by *direct fluorescent antibody* (DEA) testing.⁷⁷

MICROBIOLOGIC ASSAYS

The clinical microbiology laboratory offers a broad range of assays for diagnosis of lower respiratory tract infection. For any particular pathogen, multiple assays may be available, and therefore it is the responsibility of the clinician to choose the assay with the best performance characteristic for a particular specimen type. Table 17-6 summarizes the accuracy of assays used in the diagnosis of lower

Figure 17-1 Gram stain of sputum specimens. **A**, This specimen contains numerous polymorphonuclear leukocytes and no visible squamous epithelial cells, indicating that the specimen is acceptable for routine bacteriologic culture. **B**, This specimen contains numerous squamous epithelial cells and rare polymorphonuclear leukocytes, indicating an inadequate specimen for routine sputum culture. (From Tille P: *Bailey & Scott's diagnostic microbiology*, ed 13, Philadelphia, 2014, Mosby, Fig. 69-4.)

*Testing for acute Q fever and toxoplasmosis should be done using a battery of tests that must be interpreted together because sensitivity and specificity of individual tests are not available.

†Cross reaction is seen with *Histoplasma capsulatum*.

AIDS, acquired immunodeficiency syndrome; BAL, bronchoalveolar lavage; CSF, cerebrospinal fluid; HIV, human immunodeficiency virus; IC, immunocompromised; Ig, immunoglobulin; N/A, not available; NAT, nucleic acid test; PCR, polymerase chain reaction.

respiratory tract infections caused by bacteria, fungi, and parasites. In addition, the clinician must be familiar with the turnaround time for each assay to optimize use of the results in managing the patient.

MICROSCOPY

Microscopic examination of lower respiratory tract specimens offers a rapid approach to detection and identification of many pathogens. However, as discussed earlier, a major limitation of microscopic examination is that it cannot distinguish between infection, colonization, and contamination when the specimen is collected through the oropharynx.⁷⁸⁻⁸⁰ In addition, microscopy lacks sensitivity in specimens with less than 10⁴ CFU per milliliter. Microscopy does routinely provide valuable information on the quality of specimen and the type of inflammatory response present. Specimens demonstrating a preponderance of polymorphonuclear leukocytes, ciliated columnar epithelial cells, or alveolar macrophages with few, if any, squamous epithelial cells (<10 per low-power field) represent lower respiratory tract secretions. The presence of alveolar macrophages is a more specific marker of lower respiratory tract secretions than neutrophils and is more likely to be associated with a significantly lower incidence of oropharyngeal contamination.⁸¹ The finding of neutrophils with intracellular organisms is considered indicative of an active infectious process.⁸²⁻⁸⁴

The Gram-stained smear is an essential and necessary part of evaluation of sputum and tracheal aspirates for

determining the quality and acceptability of specimens for bacterial culture^{74,76} and for providing a rapid assessment of the most likely etiologic agent of the pneumonia. Although Gram stains might also suggest the presence of mycobacteria, fungi, and parasites, special stains should be ordered when those pathogens are suspected. The Gram stain also stains squamous epithelial cells, ciliated columnar epithelial cells, neutrophils, and alveolar macrophages, which are used for assessment of specimen quality and inflammatory response. Table 17-7 shows criteria used by the laboratory to interpret findings on Gram stain and report them to the physician. Although it is impossible to correlate every staining pattern to a particular pathogen, several Gram stain patterns are pathognomonic for a particular pathogen or clinical entity (Table 17-8).

The accuracy of Gram stain for detection of infection depends on the stringency of criteria. In assessing patients with acute CAP, Rein and colleagues⁸⁵ found that three or more gram-positive lancet-shaped diplococci (Fig. 17-2) correctly predicted the presence of pneumococci in corresponding cultures in 90% of cases, with a sensitivity and specificity of 62% and 85%, respectively. As expected, improving the sensitivity of the Gram stain examination by lowering the criteria for positivity resulted in reduced specificity in the diagnosis of pneumococcal infection. Similar levels of sensitivity of Gram-stained smears have been reported by others in identifying pneumococci as well as *H. influenzae* (Fig. 17-3) in sputum specimens from patients with acute CAP.^{86,87} For the diagnosis of pneumococcal pneumonia, a combination of Gram-stained smear and

Table 17-7 Laboratory Criteria for Reporting Gram Stain Results to the Ordering Physician

Number of Bacteria Found per Field under Oil Immersion 100× Objective	Bacterial Quantity Reported to Clinician
0	Negative
<1	1+ (rare)

6–30	3+ (moderate)
>30	4+ (heavy)

Table 17-8 Pathognomonic Gram Stain Patterns

Pattern Reported	Pathogen or Entity Suggested
Intracellular organisms	Active infection
Gram-positive cocci in pairs (lancet-shaped diplococci) and short chains	<i>Streptococcus pneumoniae</i>
Pleomorphic gram-negative coccobacilli	<i>Haemophilus influenzae</i>
Gram-negative diplococci	<i>Moraxella catarrhalis</i> *
Gram-positive cocci in clusters	<i>Staphylococcus aureus</i>
Mixed morphotypes of gram-positive and gram-negative rods, cocci, and coccobacilli	Aspiration pneumonia
Beaded gram-positive or gram-variable rods	Actinomycetales order, which includes genera <i>Mycobacterium</i> , <i>Actinomyces</i> , <i>Corynebacterium</i>
Filamentous branching gram-positive or gram-variable rods	<i>Nocardia</i> , <i>Actinomyces</i>

*Cannot be distinguished from *Neisseria meningitidis*.

Figure 17-2 Lancet-shaped diplococci in Gram-stained sputum from a case of *Streptococcus pneumoniae* pneumonia. The clear “halo” surrounding some of the diplococci (arrows) is the consequence of the thick polysaccharide capsule. (From Tille P: *Bailey & Scott’s diagnostic microbiology*, ed 13, Philadelphia, 2014, Mosby, Fig. 15-1.)

culture of sputum can yield the correct diagnosis in more than 80% of patients who received less than 24 hours of effective antibiotic therapy.⁸⁸

Direct examination of sputum for the identification of other organisms that can either be commensals or causes

Figure 17-3 Gram stain of *Haemophilus influenzae* in sputum. The small gram-negative bacilli (arrows) can be difficult to distinguish from debris. (From Tille P: *Bailey & Scott’s diagnostic microbiology*, ed 13, Philadelphia, 2014, Mosby, Fig. 32-1.)

of acute bacterial pneumonia in adults, such as *H. influenzae*, *M. catarrhalis*, and *N. meningitidis*, may also be problematic.^{7,78,80,89} Their role as etiologic agents of pneumonia is strongly suggested by the finding of large numbers of gram-negative coccobacilli (*H. influenzae*) and diplococci (*M. catarrhalis* and *N. meningitidis*) located within and outside of neutrophils in sputum specimens.^{82–84} Because sputum microscopy (and subsequent culture) can give misleading results, the diagnosis of *Haemophilus*, *Moraxella*, or meningococcal pneumonia can be confirmed only by invasive techniques. Because invasive techniques are infrequently performed to identify the etiologic agents of acute CAP, the sensitivity and specificity of sputum Gram-stained smears cannot be determined reliably in such cases. A similar challenge is faced when trying to distinguish between colonization and infection by gram-negative bacilli. For example, up to 10⁸ CFU of gram-negative bacilli per milliliter may be found in respiratory secretions of patients on mechanical ventilation in intensive care units without evidence of pneumonia.¹²

Acid-fast staining is the method of choice for visualization of mycobacteria in respiratory specimens. Laboratories may use either carbolfuchsin or fluorochrome to stain mycobacteria. Table 17-9 shows criteria used by the laboratory to report findings on the acid-fast stain. In most studies the carbolfuchsin-based stain has a sensitivity of 60% or lower compared to culture.⁹⁰ The fluorochrome stain, which uses fluorescent dye such as auramine or auramine-rhodamine to highlight mycobacteria, is on average 10% more sensitive than carbolfuchsin⁹⁰ and is therefore the method recommended by the World Health Organization for screening sputum smears for mycobacteria. The sensitivity of acid-fast microscopy depends on the bacillary burden, sample volume, host immune status, staining method, and other variables.⁹¹ The major limiting factor is that approximately 10⁴ acid-fast bacilli per milliliter of sputum must be present to be visualized under light microscopy using an acid-fast stain.⁹¹ The insensitivity of smear microscopy for TB therefore necessitates the use of more sensitive methods such as culture and nucleic acid tests.^{92,93}

In addition, although acid-fast stains have high specificity, they cannot distinguish between *M. tuberculosis* complex and nontuberculous mycobacteria, and carbolfuchsin stains also stain *Legionella micdadei* (also known as *Tatlockia micdadei*).⁹⁴ Modified acid-fast stain, a modified carbolfuchsin stain, is used for direct staining of partially acid-fast-positive organisms such as *Nocardia*, *Tsukamurella*, *Rhodococcus*, and *Gordonia*.⁵

Immunofluorescence examination by DFA staining is an alternative method for direct visualization of organisms. The diagnosis of legionellosis is usually made by a combination of direct immunofluorescence examination and culture of respiratory specimens, and antigen and antibody testing. DFA staining can be performed on sputum, endotracheal aspirate, bronchial washing, and lung tissue specimens, with sensitivities ranging from 25% to 66% for the diagnosis of *L. pneumophila* pneumonia and specificities of more than 94%⁹⁵ (Fig. 17-4). Both clinical and technical variables account for the broad range of sensitivity of this test, and the accuracy of this method for detection of pneumonia due to other *Legionella* species is less precisely known. In the absence of other supporting evidence, a positive DFA result is generally not accepted as sufficient for the diagnosis of *Legionella* infection, and other confirmatory measures should be undertaken.

DFA testing has also been found to be sensitive and specific in detecting *Chlamydia trachomatis* in nasopharyngeal

specimens from infants with pneumonia and has also been applied to sputum and BAL for detection of *P. jirovecii*, the causative agent of *Pneumocystis* pneumonia.^{96,97} Silver stain, direct immunofluorescence, indirect immunofluorescence, and Diff-Quik (a modified Giemsa stain) have all been found to have greater than 90% sensitivity for detecting *P. jirovecii* in induced sputum and BAL samples from human immunodeficiency virus (HIV)-infected patients⁹⁸ (Fig. 17-5). All of these staining techniques have lower sensitivity in patients who are not infected with HIV, but DFA is consistently more sensitive than the other staining techniques.^{99,100}

DFA has also been applied to respiratory secretions for the diagnosis of respiratory virus infections. DFA testing can be performed in 1 to 4 hours and is typically more sensitive than rapid antigen tests.^{77,101} However, DFA testing for respiratory viruses requires a high level of technical and interpretive expertise, is difficult to adapt to the high throughput required for pandemic or high-volume testing, and remains less sensitive than real-time polymerase chain reaction (PCR).^{77,102} DFA for viral detection has been phased out in many clinical laboratories as rapid, sensitive, multiplexed molecular diagnostic respiratory virus tests have become available.

The visualization of fungal elements in respiratory secretions requires the use of special stains. Historically, potassium hydroxide was used to degrade host tissue and visualize fungal elements (Fig. 17-6). Calcofluor white stain, a fluorochrome that binds to chitin and cellulose present in the fungal cell wall, is now commonly added to potassium hydroxide or used alone to provide better delineation of fungal elements (Fig. 17-7).^{103,104} Table 17-10 lists staining patterns that are suggestive of certain fungal pathogens. It is important to note that identification of fungi based on microscopic appearance of fungal elements in lung tissue or secretions is subject to error, and definitive identification must be deferred to culture.¹⁰⁵

The identification of pulmonary parasites such as *Strongyloides stercoralis* and *Paragonimus* spp. is typically made by microscopic examination of respiratory secretions. *S. stercoralis* larvae and rarely eggs can be seen on most stains but are sufficiently large that they are more likely to be found using a low-power objective (Fig. 17-12).¹⁰⁶ The diagnosis of microfilariae causing tropical pulmonary eosinophilia requires peripheral blood parasite examination of nightly blood samples because these parasites typically circulate in the blood only at night, which coincides with activity of its

insect vector.¹⁰⁷ *Echinococcus* cysts may be detected in pulmonary cyst fluid, and *Entamoeba histolytica* may be seen in association with pleural disease, if an amebic liver abscess erodes through the diaphragm.

CULTURE

Microbiologic culture of respiratory specimens allows definitive identification of the suspected pathogens and permits determination of bacterial, mycobacterial, and yeast susceptibility to antimicrobial agents. For cultivation of particular groups or species of microorganisms, laboratories must inoculate processed samples on one or more culture media supplemented with nutrients suitable for cultivation of the desired microorganisms and inhibitors

for selective inhibition of undesirable organisms. The clinician must therefore be aware that, although many organisms do grow on routine aerobic and anaerobic cultures, a number of respiratory pathogens such as *Mycoplasma*, *Legionella*, *Mycobacterium*, *Nocardia*, *Rhodococcus*, and *Histoplasma capsulatum* require pathogen-specific growth conditions (growth supplements, temperature and carbon dioxide requirements, and incubation times), which have to be specified when fastidious pathogens are part of the differential diagnosis.⁵ For example, *Legionella* species require culture media supplemented with L-cysteine and α -ketoglutarate (buffered charcoal yeast extract),⁹⁵ slow-growing mycobacteria require media enriched with a lipid extract and antimicrobials to limit the growth of oral commensals,⁹¹ and *H. capsulatum* requires extended incubation time up to 4 weeks.¹⁰⁸ Although most *Nocardia* species grow well on mycobacterial culture media as well as on ordinary bacterial and fungal culture media, optimal recovery from clinical specimens is obtained by using the same buffered charcoal yeast extract culture medium as that for the isolation of *Legionella*.¹⁰⁹

Laboratories commonly use a semiquantitative culturing method and report the number of colonies present in consecutive streaked quadrants using a 1+ to 4+ grading system. Table 17-11 lists criteria for reporting of semiquantitative cultures. It is important to note that with the semiquantitative culture method, the volume of specimen cultured is not standardized. Quantitative cultures are also performed on certain respiratory specimens such as protected catheter brush specimens and BAL fluid.¹¹⁰ Nonetheless, a randomized trial found that in mechanically ventilated patients with pneumonia, the use of quantitative BAL and nonquantitative endotracheal aspirate cultures resulted in similar clinical outcomes, although patients known to be colonized or infected with *Pseudomonas aeruginosa* or methicillin-resistant *Staphylococcus aureus* were

excluded and antibiotics were withheld until the results of culture were available.⁵² Bacteria present in quantities greater than 10³ CFU/mL in cultures of protected catheter brushes⁴⁸ and in quantities greater than 10⁴ CFU/mL in cultures of BAL fluids⁵⁰ are defined by the laboratory as positive and identified and tested for their susceptibility to appropriate antimicrobial agents.¹¹¹ The diagnostic value of break points of bacterial growth (i.e., 10³ to 10⁵ CFU/mL) depends not only on the type of microbiologic processing used but also on the relationship of two variables: the concentration of pathogens present in the BAL fluid and the degree of contamination of the bronchoscopic channel through which lavage fluid was injected and aspirated. Other variables affecting the sensitivity of BAL specimens include antibiotic administration and the volume of lavage

Figure 17-8 *Cryptococcus neoformans* with narrow-based bud; silver stain. The faintly staining capsule is also visible (arrows). (From Mandell GL, Bennett JE, Dolin R: *Principles and practice of infectious diseases*, ed 7, Philadelphia, 2010, Churchill Livingstone, Fig. 263-8.)

Figure 17-9 *Coccidioides immitis* spherules in a tissue biopsy. Spherules can also be found in fresh sputum samples. The internal endospores stain with silver (arrowhead), whereas the external wall of the spherule does not. The endospores that have been released from a spherule resemble budding yeast (arrow) (GMS stain; ×400 original magnification). (From Tille P: *Bailey & Scott's diagnostic microbiology*, ed 13, Philadelphia, 2014, Mosby, Fig. 60-31.)

fluid injected and the volume of fluid retrieved.¹¹² Diagnostic specificity depends greatly on techniques used to minimize contamination of the specimen by upper respiratory flora, such as discarding the first aliquot of aspirated fluid.¹¹³

Because many pathogens of the lower respiratory tract are also members of the oropharyngeal flora, culture results must be correlated with the Gram stain findings, including the presence or absence of polymorphonuclear leukocytes. Respiratory pathogens seen on Gram stain to be predominant with typical morphologic characteristics both within and outside polymorphonuclear leukocytes are reported and identified to the species level. Upper respiratory colonization with potentially pathogenic microorganisms, such as gram-negative bacilli, may not be related to the actual etiologic agents of lower respiratory tract infection. Sputum specimens contaminated with Enterobacteriaceae or *S. aureus* from oropharyngeal secretions may obscure the diagnosis of pneumococcal pneumonia, anaerobic pleuropulmonary infection, or even TB.¹¹⁴⁻¹¹⁷ Except

Figure 17-10 *Rhizopus* spp. in a potassium hydroxide preparation of sputum showing broad, predominantly nonseptate hyphae (arrows). Phase-contrast microscopy. (From Tille P: *Bailey & Scott's diagnostic microbiology*, ed 13, Philadelphia, 2014, Mosby, Fig. 60-2.)

Figure 17-11 Branching septate hyphae (arrows) of *Aspergillus fumigatus*. Papanicolaou staining of sputum. (From Tille P: *Bailey & Scott's diagnostic microbiology*, ed 13, Philadelphia, 2014, Mosby, Fig. 60-17.)

for *Cryptococcus*, yeasts are considered to be of upper respiratory origin and are not routinely identified.¹¹⁷

The sensitivity and specificity of cultures depend on the pathogen burden, specimen type, collection method, the cytologic screening criteria applied to ensure sampling of lower respiratory tract secretions, and the threshold of colony count to distinguish infection from contamination.

Figure 17-12 *Strongyloides stercoralis* rhabditiform larva; iodine stain. When examined under low power, staining of sputum may be unnecessary. Unfixed preparations can also show larval mobility. (From Tille P: *Bailey & Scott's diagnostic microbiology*, ed 13, Philadelphia, 2014, Mosby, Fig. 51-8.)

Table 17-11 Semiquantitative Scheme for Grading Bacterial Growth on Streaked Agar Plates

Grade	NO. OF COLONIES PRESENT IN CONSECUTIVE STREAKED QUADRANTS		
	First	Second	Third
1+	<10	0	0
2+	>10	<5	0
3+	>10	>5	<5
4+	>10	>5	>5

Based on data from Waites KB, Saubolle MA, Talkington DF, et al: *Cumitech 10A: laboratory diagnosis of upper respiratory tract infections* (Sharp SF, coordinating editor), Washington, DC, 2006, ASM Press.

In 1971 Barrett-Connor¹¹⁴ showed that only 45% of patients with bacteremic pneumococcal pneumonia had pneumococci isolated from their sputum cultures, whereas 27% of patients had moderate to heavy growth of another potential pathogen in these cultures. In contrast, fungal cultures of respiratory specimens were positive in approximately 85% of cases with disseminated or chronic pulmonary histoplasmosis.^{118,119} We now better understand how careful specimen collection, cytologic screening of specimens to discard those contaminated with oropharyngeal secretions, and use of the results of the Gram-stained smear to guide identification of isolates in culture all contribute to the diagnostic value of sputum culture in acute pneumococcal pneumonia.

It is important for the clinician to have knowledge of the turnaround time of all tests, including cultures. The time to detection of positive culture results is dependent on the number of organisms in the inoculum and the replication rate of the pathogen.¹⁰⁸ Table 17-12 shows typical turnaround times for lower respiratory tract pathogens.

Fecal culture may be useful in cases of suspected pulmonary involvement with *S. stercoralis* when sputum cytologic

Table 17-12 Time to Detection of Respiratory Pathogens in Culture

Key Respiratory Pathogens	Time to Detection in Culture
<i>Acinetobacter baumannii</i> , <i>Aspergillus</i> , <i>Coccidioides immitis</i> , <i>Coccidioides posadasii</i> , <i>Cryptococcus</i> , <i>Escherichia coli</i> , <i>Haemophilus influenzae</i> , <i>Klebsiella pneumoniae</i> , <i>Moraxella catarrhalis</i> , <i>Mycobacterium abscessus</i> group, <i>Mycobacterium chelonae</i> , <i>Neisseria meningitidis</i> , <i>Nocardia</i> ,* <i>Pseudomonas aeruginosa</i> , <i>Staphylococcus aureus</i> , <i>Streptococcus pneumoniae</i> , <i>Zygomycetes</i>	1–3 days
<i>Actinomyces</i> , <i>Legionella</i> ,* <i>Sporothrix schenckii</i>	3–5 days
<i>Blastomyces dermatitidis</i> , <i>Histoplasma capsulatum</i> , <i>Mycobacterium avium-intracellulare</i> complex, <i>Mycobacterium tuberculosis</i> complex, <i>Mycoplasma pneumoniae</i>	1–4 weeks

*May take longer.

examination fails to identify larvae. The agar plate method, which looks for tracking of bacteria by the motile larvae, is a useful adjunct to standard microscopic fecal examination and may be up to six times more sensitive.¹²⁰⁻¹²³

Viral culture techniques previously played an important role in the diagnosis of respiratory virus infections.¹²⁴ However, traditional viral culture is laborious, requires significant technical and interpretive expertise, allows the isolation of only a limited range of disease-causing viruses, and has a long turnaround time that limits clinical utility.¹²⁵ Shell vial culture is an improved method in which a sample is centrifuged onto a layer of cells, with subsequent detection of viral antigen. Shell vial cultures, particularly those using a mixture of mink lung and A549 cells, provide equivalent to improved sensitivity compared to traditional culture, with more rapid turnaround time.¹²⁶⁻¹²⁸ Similar to respiratory virus DFA, routine respiratory viral cultures are being phased out in many clinical laboratories with the widespread availability of respiratory virus molecular diagnostic tests. However, in BAL samples from transplant recipients and other immunocompromised patients, shell vial cultures using human fibroblast cell lines may be clinically useful for detection of *cytomegalovirus* (CMV)^{129,130} and traditional viral cultures may be useful for recovery of herpes simplex virus.¹³¹⁻¹³³

ANTIMICROBIAL SUSCEPTIBILITY TESTING

Antimicrobial susceptibility testing is performed to assist clinicians with the selection of appropriate targeted antibiotic therapy to optimize clinical outcomes. There are several aspects of this in vitro testing that are important to understand. First of all, testing methods and interpretation of results must be done according to accepted standards, such as the *Clinical and Laboratory Standards Institute* (CLSI), the U.S. *Food and Drug Administration* (FDA), or the *European Committee on Antimicrobial Susceptibility Testing* (EUCAST)

for the various categories of organism. Second, the selection of antibiotics to test and report is determined in collaboration with CLSI/EUCAST guidelines, the hospital formulary, infectious disease specialists, the pharmacy, and the infection prevention committee. Third, antimicrobial susceptibility testing should not be performed when the pathogen has a predictable susceptibility profile (e.g., all *Streptococcus pyogenes* are currently susceptible to penicillin), nor is susceptibility testing needed for a specific antibiotic when an organism has intrinsic resistance to that antibiotic (e.g., *Enterobacter* spp., *Klebsiella* spp., *Citrobacter* spp., and *Serratia* spp. are all intrinsically resistant to ampicillin). The bacterial pathogens from the lower respiratory tract, for which the susceptibility profile is not predictable and thus antimicrobial susceptibility testing is commonly performed, are *S. pneumoniae*, *S. aureus*, *H. influenzae*, *M. catarrhalis*, the Enterobacteriaceae, *P. aeruginosa*, and other nonfermenting gram-negative rods. Fourth, because antimicrobial susceptibility testing measures in vitro activity, other factors must be considered when determining in vivo activity, including antimicrobial pharmacokinetics and pharmacodynamics and patient-specific factors such as immune status.

Phenotypic susceptibility testing methods used by the clinical laboratory consist of the disk diffusion method, which generates a qualitative result based on the zone size of bacterial growth inhibition, and the dilution method, which generates a quantitative result: the minimum inhibitory concentration. Results generated by each method are reported as: “susceptible,” “intermediate,” or “resistant.” Susceptible implies the organism will likely respond to treatment with the antibiotic at a standard dosage. Intermediate may be effective if higher dosing can be used (e.g., β -lactams) or the antibiotic being used concentrates at the site of infection (e.g., fluoroquinolones for urinary tract infections). Resistant implies the organism is not likely to respond to therapy with that antibiotic. The interpretation criteria (susceptible, intermediate, resistant) are specific to each organism-drug combination as well as to pharmacokinetic (e.g., peak serum levels, protein binding, and clearance rate of the drug) and pharmacodynamic (e.g., whether the rate of bacterial killing is concentration dependent) characteristics of each drug. Therefore, because the measurement of the minimum inhibitory concentration alone does not capture these multiple considerations, simply choosing a drug on the basis of the lowest minimum inhibitory concentration in a susceptibility report is not recommended.

Genotypic susceptibility testing is also possible for certain pathogen-drug combinations when a monogenic mutation accurately predicts a resistant phenotype. Examples include the *mecA* gene for methicillin resistance in *Staphylococcus*,¹³⁴ *vanA* and *vanB* for vancomycin resistance in *Enterococcus*,¹³⁵ and specific *rpoB* mutations in rifampin resistance in *M. tuberculosis*.¹³⁶

Not all pathogens isolated in the laboratory can be reliably tested for antimicrobial susceptibility. For organisms such as *Chlamydia*, *Mycoplasma*, *Legionella*, nontuberculous mycobacteria, and molds, there are currently no standard test methods or interpretive criteria. For these pathogens, clinical experience, use of consensus guidelines, and careful assessment of patient response to antimicrobial therapy is most valuable for optimal patient management.

NUCLEIC ACID TESTS

In recent years, technological advances in *nucleic acid testing* (NAT) and instrument automation have revolutionized the simplicity, speed, and accuracy of detecting fastidious pathogens directly from respiratory specimens.¹³⁶⁻¹³⁸ In many laboratories these tests have replaced conventional, less sensitive, more laborious methods for routine use. With the unique capabilities of molecular diagnostic tests and the need for rapid, sensitive detection of respiratory pathogens, molecular assays will continue to gain an increasing role in the diagnosis and management of patients with opportunistic and community-acquired pneumonia. Most NATs are based on amplification and detection of nucleic acid targets specific to the pathogens of interest. NATs offer several advantages over conventional direct examination, microbiologic cultures, and serologic assays. First, NATs have the ability to detect and identify pathogens rapidly (in hours). Second, NATs provide the only means of detection for some microorganisms that are difficult or impossible to grow in culture. Certain viruses, for example, are very difficult to cultivate by conventional culture-based methods, and NATs enable detection of these organisms in clinical specimens.¹³⁹ Third, NATs make possible detection of pathogens, such as *M. tuberculosis*, in resource-limited settings where laboratory infrastructure for culture is lacking.^{140,141} Finally, for some pathogens, NATs allow determination of antimicrobial susceptibility directly from respiratory tract specimens.

A number of commercial and in-house NATs are available for direct detection of *M. tuberculosis* in sputum. These assays can yield results in 2 to 8 hours. For example, in comparison to conventional cultures for *M. tuberculosis*, NATs have high sensitivities (86% to 97%) and specificities (98%) in smear-positive respiratory samples.⁹¹ In smear-negative, culture-positive specimens, NATs can confirm the presence of *M. tuberculosis* in 33% to 96% of samples, weeks earlier than culture.⁹¹ The sensitivity further improves with smear-negative sputa if the assay is performed on one to two additional samples.¹³⁶ Detection of *M. tuberculosis* susceptibility to first- and second-line drugs can also be accomplished directly from sputum.^{142,143} Commercial NATs detect rifampin and isoniazid resistance with sensitivity of 94% to 99% and 88% to 95%, respectively.^{91,143-145} Based on the improved performance of NATs over smear microscopy and the rapid turnaround time compared to culture, the U.S. Centers for Disease Control and Prevention (CDC) recommended that NAT “testing should be performed on at least one respiratory specimen from each patient with signs and symptoms of pulmonary TB for whom a diagnosis of TB is being considered but has not yet been established, and for whom the test result would alter case management or TB control activities.”⁹³ In addition, the World Health Organization has recommended the use of NATs to screen for multidrug-resistant TB. Three such NATs are commercially available in Europe and elsewhere, and one has been approved by the FDA as of 2014.

Diagnostic methods have also been described for detecting the nucleic acids of *C. pneumoniae*,^{7,41,42} *M. pneumoniae*,^{40,44,45} *L. pneumophila*,⁴⁰ dimorphic fungi,¹⁴⁶ monomorphic fungi,¹⁴⁷⁻¹⁵⁰ *P. jirovecii*,^{151,152} *Toxoplasma gondii*,¹⁵³ respiratory viruses,¹³⁹ herpes simplex virus,¹³²

and CMV^{154,155} directly in respiratory specimens of normal and immunocompromised hosts. Accuracy studies have indicated that most of these assays are at least comparable to, if not better than, conventional culture, direct antigen, and/or serologic detection methods, especially when examining respiratory specimens that contain low numbers of pathogens. For example, a rapid PCR assay has been applied for the diagnosis of an outbreak of *Chlamydia psittaci* that resulted from transmission of this infectious agent to humans from birds purchased in stores; in this outbreak, PCR detected 50% more cases than did culture.¹⁵⁶ Compared to culture and serologic tests, PCR was also shown to be the most sensitive method for detection of *C. pneumoniae* during an outbreak of CAP.¹⁵⁷ However, NAT results should be interpreted with caution because NATs currently cannot differentiate between organisms that inhabit the upper airway without causing disease and those that are responsible for the patient's illness. For example, as mentioned, *S. pneumoniae*, *C. pneumoniae*, and *M. pneumoniae* may inhabit the upper airway without causing disease.^{6,10} Similarly, the lowered diagnostic specificity of *P. jirovecii* NATs is likely due to the detection of *P. jirovecii* nucleic acid from cysts that are present in low numbers and in a latent state in pulmonary tissues of asymptomatic patients.¹⁵⁸⁻¹⁶⁰

In patients with culture-negative infection, or when cultures were not performed on a tissue biopsy sample before fixation, a broad-range PCR assay coupled with amplicon sequencing can be used for detection and identification of bacterial and fungal DNA from fresh or *formalin-fixed paraffin-embedded* (FFPE) specimens.¹⁶¹⁻¹⁶⁴ The bacterial 16S ribosomal RNA gene and the fungal ribosomal RNA operon (encoding 5.8S, 18S, 28S ribosomal subunit genes with the internal transcribed spacer regions [ITS1 and ITS2]) are the most reliable and frequently used targets for identifying bacterial and fungal sequences, respectively.¹⁶⁵ As with all NATs, sensitivity is higher from fresh tissue than from FFPE specimens: for example, fungal sequencing was successfully completed on 97% of specimens when performed on fresh specimens compared to 63% to 70% when performed on FFPE specimens.¹⁶³ Despite the many advantages of direct bacterial and fungal identification by sequencing, clinicians must be aware that the success of this method is dependent on the amount of specimen submitted (e.g., open biopsy versus needle biopsy), the pathogen burden, and whether fresh versus FFPE tissue is tested. It is imperative that testing is strictly limited to samples obtained from sterile sources because contamination of the sample with commensal organisms or environmental spores could yield false-positive results and lead to mismanagement of the patient.^{163,164} Sequence results must always be correlated with clinical, histopathologic, and ancillary test results (antibody or antigen detection) to ensure the clinical accuracy of sequence results.

The diagnosis of respiratory virus infections (Table 17-13) has been revolutionized by nucleic acid amplification testing.¹³⁹ These tests are now considered more sensitive than all other current methods of virus detection, including viral culture and DFA testing, discussed earlier, as well as rapid antigen tests, discussed later. Following the 2009 influenza A H1N1 pandemic, there was a tremendous increase in the availability and widespread implementation of real-time PCR assays for influenza and other respiratory

Table 17-13 Respiratory Viruses

STANDARD RESPIRATORY VIRUS TEST PANEL

Influenza A, B
Respiratory syncytial virus
Human *Metapneumovirus*
Parainfluenza 1, 2, 3
Adenovirus

EXPANDED RESPIRATORY VIRUS PANEL (MAY INCLUDE ONE OR MORE)

Rhinovirus
Enterovirus*
Human *Coronavirus* (229E, HKU1, OC43, NL63)
Human bocavirus (HBoV)[†]

ADDITIONAL VIRUSES TO CONSIDER IN THE IMMUNE COMPROMISED

Cytomegalovirus
Herpes simplex virus
Varicella-zoster virus
Human herpesvirus 6

OTHER VIRUSES THAT CAUSE LOWER RESPIRATORY TRACT INFECTION

Hantavirus
Measles virus
Parechovirus
Parainfluenza virus 4
Influenza C
Polyomavirus (BK, WU, K1)

EMERGING SEVERE ACUTE RESPIRATORY VIRUSES

Avian influenza (H5N1, H7N9)
Human coronavirus—severe acute respiratory syndrome
Human coronavirus—Middle Eastern respiratory syndrome

*Commercial multiplex nucleic acid amplification tests may not distinguish between *Rhinovirus* and *Enterovirus*.
[†]Human bocavirus detection in respiratory specimens is of uncertain clinical significance, though this virus is included in several commercial multiplex nucleic acid amplification tests.

viruses. These real-time PCR assays include those endorsed by the CDC, as well as numerous laboratory-developed and commercially produced tests.¹³⁹ However, in-house real-time PCR tests are of high complexity, requiring experienced and highly skilled staff, as well as specialized molecular diagnostic laboratory facilities. Furthermore, these tests are generally batched, thereby prolonging the turnaround time and reducing clinical utility. Finally, real-time PCR allows only a moderate level of multiplexing (i.e., use of primers and probes for detecting multiple targets in the same reaction), a potential issue for detecting a broad range of respiratory viruses with a limited number of reactions. To address these issues, a variety of commercial test systems have been developed, though no single system provides comprehensive detection of clinically relevant respiratory viruses with optimal sensitivity in a format that can be performed at or near the point of care. Three groups of molecular testing now exist, with different levels of technical and personnel demands (referred to as moderate or high complexity, as established by the Clinical Laboratory Improvement Amendments).

One group of molecular tests includes limited respiratory virus panels of moderate complexity on FDA-cleared, sample-to-answer platforms that combine the speed and

simplicity of rapid antigen tests with the sensitivity of nucleic acid amplification. These tests include Xpert Flu (Cepheid; Sunnyvale, CA), which detects influenza A and B in about 1 hour, and Verigene Respiratory Virus Plus (Nanosphere; Northbrook, IL), which detects and subtypes influenza A and B, and detects and types *respiratory syncytial virus* (RSV) in less than 2½ hours. Though more sensitive than traditional respiratory virus diagnostics, Xpert Flu is slightly less sensitive than in-house real-time PCR assays.^{101,166-171} Performance of the Verigene Respiratory Virus Plus appears comparable to in-house real-time PCR.¹⁷² These assays have not yet been compared to each other.

A second group of tests are the high-complexity, FDA-cleared, comprehensive respiratory virus panels that require separate extraction and PCR amplification steps before multiplex nucleic acid detection. These tests include the xTAG Respiratory Virus Panels (Luminex; Austin, TX): xTAG RVPv1 and xTAG RVP FAST, as well as the eSensor Respiratory Virus Panel (GenMark Diagnostics; Carlsbad, CA). The xTAG RVPs achieve high-level multiplexing through the combination of target amplicon labeling with universal, minimally cross-hybridizing, complementary oligonucleotide sequences and flow cytometric detection using a solution-phase array composed of spectrally distinct microspheres.¹⁷³ In approximately 8 hours, RVPv1 detects influenza A, including subtyping H1 and H3, influenza B, RSV A, RSV B, parainfluenza virus 1, 2, and 3, human metapneumovirus, adenovirus, and rhinovirus/enterovirus. Compared to RVPv1, RVP FAST has a shorter time to result (about 6 hours); however, it does not detect the parainfluenza viruses, and it does not distinguish between RSV types. Several studies have compared the clinical performance of the xTAG RVPs and found that both the xTAG RVPv1 and RVP FAST panels are more sensitive than traditional respiratory virus testing methodologies, less sensitive than in-house real-time PCR, and that RVPv1 is more sensitive than RVP FAST.¹⁷⁴⁻¹⁸⁰ Of note, these assays demonstrate low sensitivity for adenoviruses and do not distinguish between the closely related picornaviruses, rhinovirus, and enterovirus.

In this same group the eSensor RVP achieves high-level multiplexing through competitive hybridization and electrochemical detection using a microfluidic device containing an array of single-stranded oligonucleotide capture probes. In approximately 8 hours the eSensor RVP detects influenza A, including H1, 2009 H1, and H3 subtyping, influenza B, RSV A, RSV B, parainfluenza virus 1, 2, and 3, human metapneumovirus, adenovirus C, adenovirus B/E, and rhinovirus. The eSensor RVP demonstrates comparable performance to in-house real-time PCR, including detection of adenovirus and rhinovirus, and at this time appears to be the most sensitive of the multiplex respiratory virus assays.^{180,181} Both the xTAG and eSensor RVP assays have research-only versions or versions approved outside of the United States that offer detection of parainfluenza 4, human coronaviruses 229E, HKU1, OC43, and NL63 and, for xTAG RVP, bocavirus and the severe acute respiratory syndrome coronavirus. Determination of the clinical utility of these expanded panels requires additional study.

The third group of molecular respiratory virus tests are of moderate complexity and combine the simplicity and

speed of rapid antigen testing with the sensitivity and multiplexing capability of the xTAG or eSensor RVP. At present, one assay is available in this category: the FilmArray Respiratory Panel (BioFire Diagnostics; Salt Lake City, UT), which integrates sample preparation, nested-PCR amplification, real-time fluorescent detection, and analysis in a single assay pouch.¹⁸² In about 1 hour, including less than 5 minutes of hands-on time, this assay detects influenza A, including H1, 2009 H1, and H3 subtyping, influenza B, RSV, parainfluenza virus 1, 2, 3, and 4, human metapneumovirus, adenovirus, rhinovirus/enterovirus, and human coronaviruses 229E, HKU1, OC43, and NL63. In addition, it detects three bacterial species: *Bordetella pertussis*, *C. pneumoniae*, and *M. pneumoniae*. Clinical performance is similar to xTAG RVPv1, demonstrating higher sensitivity than traditional respiratory virus testing methodologies and lower sensitivity compared to in-house real-time PCR.^{177,179,180,183-188} The current Film Array Respiratory Panel also has low sensitivity for adenoviruses, does not distinguish between rhinovirus and enterovirus, and has low throughput, because only one test can be performed on an instrument at a time. However, its rapid turnaround and ease of use allows most laboratories to perform multiplexed molecular respiratory virus testing. In the future it is expected that assays in this category will improve sensitivity, specificity, and throughput to create optimal, rapid multiplex molecular respiratory virus tests.

Given the variety of nucleic acid tests that are currently available for the diagnosis of respiratory virus infection and the rapid development of new NATs, it is important to communicate with the laboratory to confirm the viruses included in the local panel, the expected turnaround time, and local test performance characteristics. Furthermore, note that nasopharyngeal swabs and aspirate/washes are the only specimen types that have received FDA clearance so far, so it is also important to verify that the local laboratory has validated the use of lower respiratory tract specimens in their test system before sending such samples for testing.

ANTIGEN TESTING

The diagnosis of lower respiratory tract infections can be aided by detection of pathogen-specific antigens in serum or other body fluids. Antigen detection offers an alternative to direct examination of infected tissue and may play a role in the detection of pathogens that grow poorly, or not at all, in culture.

Urinary antigen assays may have value for adults with *S. pneumoniae* and *L. pneumophila* infections. In a meta-analysis of 27 studies using a composite of culture tests as the reference standard, the pooled sensitivity for direct antigen detection of *S. pneumoniae* in the urine of adults with CAP was 74% (95% confidence interval [CI], 67% to 82%) and specificity was 97% (95% CI, 93% to 100%).¹⁸⁹ In children, pneumococcal antigen in urine is less specific for invasive infection, because it was detected in 43% of children with only nasopharyngeal colonization.¹⁹⁰ Similarly, in children with pneumonia, detection of *H. influenzae* type B antigens in urine is of potential diagnostic value, but transient antigenuria may follow immunization with *H. influenzae* type B conjugate vaccine.¹⁹¹ In the evaluation of adults for

legionnaires' disease, urine *L. pneumophila* serogroup 1 antigen has a high negative predictive value with pooled sensitivity of 74% (95% CI, 68% to 81%) and specificity of 99% (95% CI, 98% to 100%).¹⁹² Urine antigen for *L. pneumophila* is detectable in 80% to 89% of patients with legionnaires' disease beginning with the first 3 days of symptoms and continuing for at least 14 days; the duration of antigenuria was reduced by antibiotic therapy and was detectable for up to 42 days, especially in immunocompromised patients.¹⁹³ The urinary antigen assays are limited to detection of infections due to *L. pneumophila* serogroup 1 and not other *Legionella* serogroups or species.⁹⁴

Detection of fungal antigen in serum, urine, and other body fluids is used as an aid in the diagnosis of infections due to *Cryptococcus neoformans*, *Aspergillus*, *H. capsulatum*, and *P. jirovecii*. Assays to detect capsular polysaccharides of *C. neoformans* in serum or cerebrospinal fluid are essential for rapid diagnosis of cryptococcosis. Commercially available assays show sensitivity ranging from 83% to 97% and specificity from 93% to 100%.¹⁹⁴ Cryptococcal antigen may also be detectable in pleural fluid and BAL fluid of patients with cryptococcal pneumonia.^{195,196} Serial measurement of serum antigen titers over time is not useful for management of patients with pulmonary cryptococcosis.¹⁹⁷ Cryptococcal antigen may be falsely positive due to the presence of rheumatoid factor or heterophile antibodies (i.e., antibodies produced to poorly defined antigens with weak affinity and multispecific activities) and falsely negative due to the prozone effect (antigen excess), localized infection, infection with a poorly encapsulated strain, or low organism burden.¹⁹⁴

Several commercial *H. capsulatum* antigen assays with variable accuracies are available for diagnosis of histoplasmosis.¹⁹⁸ The polysaccharide antigen of *H. capsulatum* can be detected in urine in approximately 90% of patients with disseminated disease and 75% with diffuse acute pulmonary histoplasmosis.^{118,119} A recent multicenter study identified antigenuria in 91.8% of 158 patients with disseminated histoplasmosis, 83.3% of 6 patients with acute histoplasmosis, 30.4% of 46 patients with subacute infection, and 87.5% of 8 patients with chronic histoplasmosis; antigenemia was detected in 100% of 31 patients with disseminated infection.¹⁹⁹ Urinary *Histoplasma* antigen levels persist during ongoing active infection, become undetectable with successful therapy, and rise with relapse of infection. The specificity of the *Histoplasma* antigen assay was 99% in patients with nonfungal infections and in healthy controls¹⁹⁹; however, the assay is known to yield positive results in patients with disseminated infections caused by *Blastomyces dermatitidis*, *Coccidioides immitis*, *Paracoccidioides brasiliensis*, *Aspergillus*, and *Penicillium marneffei*.^{200,201} Cross reactivity of the assay has not been observed in patients with invasive candidiasis, cryptococcosis, or other opportunistic systemic mycoses.²⁰⁰

At least one commercial laboratory offers antigen tests for the diagnosis of coccidioidomycosis and blastomycosis, but both tests exhibit significant cross reaction with *H. capsulatum*.²⁰²

Aspergillus galactomannan is a major cell wall component of the fungus, and detection of this antigen has been studied in many different clinical situations. Galactomannan detected in serum by enzyme immunoassay can aid in

the early diagnosis of invasive pulmonary aspergillosis, with pooled diagnostic sensitivity of 71% (95% CI, 68% to 74%) and specificity of 89% (95% CI, 88% to 90%) for proven cases of invasive aspergillosis.²⁰³ The reported sensitivity and specificity range from 40% to 100% and 56% to 100%, respectively, in various patient groups.^{17,147,204-206} The Platelia *Aspergillus* test (Bio-Rad Laboratories, Hercules, CA), a commercially available assay that detects galactomannan from *A. fumigatus*, *A. flavus*, *A. niger*, *A. versicolor*, and *A. terreus*, has been shown to yield positive results at an early stage of infection, with positive and negative predictive values of more than 90% in high-risk patients who were tested biweekly.²⁰⁴ However, this assay may cross react with *Histoplasma*, *P. brasiliensis*, *Penicillium*, *Paecilomyces*, *Alternaria*, and *Cryptococcus*,²⁰⁶⁻²⁰⁸ and false-positive galactomannan antigen assay results can be observed in patients receiving certain foods or intravenous piperacillin-tazobactam, amoxicillin, or ticarcillin.²⁰⁸⁻²¹¹ Cross reactivity with *Listeria monocytogenes* has also been reported.²¹² BAL fluid specimens from lung transplant recipients have also been evaluated for testing by *Aspergillus* galactomannan detection assay, with sensitivity of 82% and specificity of 96%.²¹³ Of note, the Plasma-Lyte (Baxter International Inc., Deerfield, IL) solution commonly used to perform BAL has been found to yield false-positive results with the Platelia *Aspergillus* test.²¹⁴ Overall, assays for galactomannan show promise, but currently a single positive result has limited value and cross reactivity is common.

Another fungal antigen used for the diagnosis of invasive fungal infection is (1→3)- β -D-glucan, which is a component of the outer cell wall of saprophytic and pathogenic fungi except Zygomycetes (*Mucor* and *Rhizopus* species) and *Cryptococcus* species.^{204,215} This antigen has been detected in serum or other body fluids of patients with invasive aspergillosis, invasive candidiasis, and infections caused by *Fusarium*, *Acremonium*, *Trichosporium*, *Scedosporium*, *Saccharomyces*, and *P. jirovecii*.^{149,216,217} A meta-analysis for diagnosis of invasive fungal infection showed a pooled sensitivity of 77% (95% CI, 67% to 84%), and specificity of 85% (95% CI, 80% to 90%).²¹⁸ Use of different assay cutoff values may result in differences in sensitivity and specificity among the various commercially available assays for detecting this antigen.^{215,219} For the diagnosis of *Pneumocystis* pneumonia in HIV-positive patients, the sensitivity of the (1→3)- β -D-glucan assay was 92% and specificity was 65%.²²⁰ In pneumocystis pneumonia, β -D-glucan levels do not correlate with organism burden, *Pneumocystis* pneumonia severity, or response to therapy.²²⁰ Cross reactivity of β -D-glucan assays has been reported with the use of cotton gauzes, swabs, packs, pads, or sponges for wound care or surgery; cellulose filters in hemodialysis patients; and various antimicrobial agents including piperacillin-tazobactam.^{215,221}

Rapid antigen tests for influenza A and B are commonly used in both ambulatory and inpatient settings. Rapid detection of influenza is critical to allow prompt treatment with antiviral agents, to reduce the risk for further transmission through implementation of infection control practices, and to reduce inappropriate use of antibiotics.^{222,223} A meta-analysis evaluating 159 studies and 26 different rapid influenza antigen tests reported a sensitivity of 62% (95% CI, 58% to 67%) and a specificity of 98% (95% CI,

98% to 99%).^{223,224} Because of this low sensitivity, physicians should consider following negative rapid influenza antigen tests with more sensitive testing, particularly if specimens are collected during times of high influenza prevalence.²²⁵ Rapid antigen tests for RSV are also available and may similarly aid in patient triage, infection control, and antibiotic management, particularly in pediatric patients. The sensitivities and specificities of these RSV rapid antigen tests range from 59% to 89% and 93% to 100%, respectively.^{124,226}

SEROLOGIC TESTING AND INTERFERON- γ RELEASE ASSAYS

The cause of lower respiratory tract infections can be suggested by detection and quantitation of humoral (e.g., antibody) responses to pathogens. In addition, *latent TB infection* (LTBI) can be diagnosed by detection of cellular immune responses to *M. tuberculosis* antigens, such as the *interferon- γ release assays* (IGRAs). Serologic testing is used commonly to identify infections due to pathogens that are difficult to detect by other conventional methods, to evaluate the course of an infection, and to determine the nature of the infection (primary infection versus reinfection, acute versus chronic infection). Serologic testing and IGRAs are less sensitive in patients with compromised immune systems and therefore cannot be used to rule out infection.²²⁷⁻²²⁹ When possible, microbiologic culture and NATs on respiratory secretions or lung tissue should be performed to detect and confirm the presence of pathogens in immunosuppressed patients who may not be able to mount antibody or cell-mediated immune responses.

The serologic methods commonly used in diagnostic laboratories include enzyme immunoassay, immunoprecipitation, *immunodiffusion* (ID), *complement fixation* (CF), immunoblotting (including Western blot), agglutination, hemagglutination inhibition, and indirect immunofluorescence assay. Serologic results are often expressed as a titer, which is the inverse of the greatest dilution, or lowest concentration of a patient's serum that retains measurable specific antibody-antigen reactivity (e.g., dilution of 1:16 = titer of 16). A fourfold or greater rise in antibody titer between acute and convalescent sera is usually required for diagnosis. An elevated pathogen-specific IgM antibody titer in a single serum sample suggests recent infection, and a falling titer provides further support for the etiologic significance of this organism. However, false-positive *immunoglobulin* (Ig) M antibody tests are not rare. Thus serologic testing of pathogen-specific IgG antibody in acute and convalescent sera remains the approach to establish a specific microbial cause of the infection.²³⁰

Various commercial assays are available for detection of specific IgM and/or IgG antibodies to respiratory tract pathogens.²³¹ These assays are useful for supporting or confirming the diagnosis of bacterial infections caused by *C. pneumoniae*, *Legionella* species, *F. tularensis*, *Y. pestis*, *C. trachomatis*, *C. pneumoniae*, *C. psittaci*, and *Coxiella burnetii*. Although antibody testing is commonly used for the detection of infection with *M. pneumoniae*, a recent study was unable to distinguish between infection and asymptomatic colonization with this organism.¹⁰ The diagnosis of *C. pneumoniae* infection can also be a problem. In some additional

instances, such as infection with *M. tuberculosis*, commercial serologic tests have been shown to be inconsistent and imprecise, which is the basis of World Health Organization policy statement advising against use of existing serologic tests in TB.²³²

M. pneumoniae infection is often diagnosed by the presence of specific antibodies in serum.²³³ Cold agglutinins, detected by agglutination of type O Rh-negative red blood cells at 4° C, are present in the sera of approximately 50% of patients with *M. pneumoniae* infection, and levels decline to baseline within 6 weeks after acute infection.²³³ However, cold agglutinins are nonspecific. Antibodies to a chloroform-methanol glycolipid extract of *M. pneumoniae* are detected by a CF test in more than 85% of culture-positive patients; a single elevated titer of greater than 80 or a greater than fourfold rise in titer between acute and convalescent sera is required to establish a diagnosis. Enzyme immunoassays to detect IgM and IgA antibodies that specifically recognize *M. pneumoniae* membrane proteins have been developed with improved sensitivity and specificity over the CF assay.²³³ Specific IgM antibodies appear during the first week of illness and reach peak titers during the third week. However, the IgM antibodies to *M. pneumoniae* are not consistently produced in adults because of prior sensitization, so that a negative IgM result does not rule out acute *M. pneumoniae* infection, particularly in older adults. Detection of specific IgA antibodies in the serum has been shown by one group to be a reliable approach for diagnosis, because these antibodies are also produced early in the course of disease and more reliably present in the infected individuals regardless of age.²³³ Others, however, found them of little value.¹⁰

Serologic testing plays an important role in the diagnosis of fungal respiratory tract infections due to *C. immitis* and *H. capsulatum*.²³⁴ For *C. immitis* a diagnosis of infection can be based on detection of antibodies to antigens derived from the coccidioidal mycelia or spherules, although there may be cross reactivity with other yeasts and dimorphic fungi. Antibodies to *C. immitis* can be detected by ID, CF, and enzyme immunoassay. Precipitin-specific IgM antibodies develop in up to 75% of individuals within 2 to 3 weeks after primary *C. immitis* infection and subsequently disappear except in patients with disseminated infection. Complement-fixing IgG antibodies appear later and persist in relation to the severity of disease, but decline with disease remission. Titers of 32 or higher suggest the possibility of disseminated infection.^{235,236} The sensitivity of serologic testing drops 8% to 20% in immunocompromised hosts compared to immunocompetent patients.²³⁷

For *H. capsulatum*, serum antibodies are detected by CF using both yeast and mycelial antigens and an ID assay, which show increased titers in more than 90% of patients with pulmonary histoplasmosis and approximately 80% with disseminated disease.¹¹⁹ The CF test is more sensitive but less specific than the ID test for the diagnosis of subclinical and acute pulmonary histoplasmosis.²³⁸ Antibodies become detectable first by CF at 2 to 6 weeks after *Histoplasma* infection and then by ID 2 to 4 weeks later. However, the ID test remains positive longer than the CF test after resolution of infection, becoming negative 2 to 5 years later. Antibody levels remain high in those with chronic pulmonary infection, progressive disseminated disease, or

mediastinal fibrosis. Commercially available serologic tests for blastomycosis exist but suffer from limited accuracy and are of minimal value in patient care.²³⁹

Serologic testing is also useful for diagnosis of parasitic infections, especially *Paragonimus*, *T. gondii* and *S. stercoralis*,^{240,241} and for diagnosis of extraintestinal *E. histolytica* disease. Serologic testing plays an especially important role for screening prospective organ transplant recipients and other patients considered for immunosuppressive therapies.

Serologic testing plays a limited role as an aid to the diagnosis of respiratory viral infections. Although detection of recent respiratory virus infection, for example with influenza A, may be determined via seroconversion or a fourfold or greater rise in antibody titer in a convalescent relative to an acute serum sample, the requirement for two temporally distinct specimens makes serologic results unlikely to factor in clinical decision making.²⁴² In contrast, routine CMV serologic testing in transplant donors and recipients provides valuable information about the risk for subsequent CMV-related sequelae, including the development of respiratory disease.²⁴³

IGRAs are in vitro assays used to measure T-cell responses to *M. tuberculosis*-specific antigens, such as ESAT-6, CFP-10, and TB7.7.²⁴⁴ Two FDA-approved commercial IGRAs are currently available: the *QuantiFERON-TB Gold In-Tube* assay (QFT-GIT; Qiagen, Carnegie, Australia) and the T-SPOT.TB assay (Oxford Immunotec, Abingdon, United Kingdom). IGRAs were developed as an alternative to the *tuberculin skin test* (TST) for diagnosis of LTBI.^{245,246} Compared to the TST, IGRAs have improved specificity for distinguishing between the responses due to *bacillus Calmette-Guérin* (BCG) vaccination and latent TB infection, because the antigens used in IGRAs, ESAT-6 and CFP-10, are absent from all strains of BCG. Also, compared to the TST, IGRAs offer logistical advantages because they do not depend on accurate intradermal injection and patients do not have to return to a health facility for the result to be read.²⁴⁴ However, like TSTs, IGRAs cannot distinguish between LTBI and active disease.²⁴⁷ The sensitivity of IGRAs in culture-positive active TB cases has ranged from 65% to 100%,^{244,248,249} and the sensitivity in patients with LTBI who progressed to active TB ranged from 40% to 100%.²⁵⁰ Both IGRAs and the TST have been shown to have similar sensitivity in adults in low- and middle-income countries.²⁵¹ However, the accuracy of IGRA testing appears to falter at the borderline levels of positivity. Studies conducted in health care workers in low-incidence settings have shown highly variable IGRA results with serial testing. The rate of conversions (negative to positive result using the manufacturer- and CDC-recommended cutoff of ≥ 0.35 IU/mL) ranged from 2% to 15%, and the rate of reversions (positive to negative result) ranged from 20% to 40%.^{252,253} Those with borderline results around the assay cutoff are more likely to revert or convert. Finally, there are limitations to the use of IGRAs. IGRA results have not proven useful for monitoring response to TB treatment. Similarly, IGRAs are no more able than the TST to predict which patients with positive results will go on to develop active TB.^{254,255} Currently, therefore, IGRA is most useful as an alternative to the TST, especially in subject populations with a high incidence of BCG vaccination.

ACKNOWLEDGMENT

We thank Stanford Pathology residents Natalia Isaza, Albert Tsai, and Lee Frederick Schroeder for contributing to this chapter.

Key Points

- Diagnostic testing should be ordered only if the result will alter treatment decisions.
- The clinician plays a critical role in preventing accidental laboratory exposure by notifying the microbiology laboratory when highly virulent and transmissible agents are suspected as the cause of disease.
- Syndromic order sets can improve the accuracy and efficiency of test selection and thus facilitate accurate diagnosis of infectious diseases.
- Lower respiratory tract secretions collected through the oropharynx are nearly always contaminated with resident microflora of the oral cavity, and therefore microscopy, culture, and nucleic acid test results must be interpreted in the context of other clinical evidence and diagnostic findings.
- Nucleic acid tests can facilitate rapid and accurate diagnosis of lower respiratory tract infections, especially those caused by viruses and pathogens that are difficult to culture.

INTRODUCTION

Imaging plays a major role in the detection, diagnosis, and serial evaluation of thoracic disease. The appropriate use of imaging techniques requires some basic understanding of the technical aspects of and abnormal findings visible with different imaging techniques and of the diagnostic accuracy of these techniques. It is not the intent of this chapter to provide a complete description of the techniques involved or an encyclopedic catalogue of radiographic abnormalities of chest diseases. Rather, this chapter is intended to provide a general survey of the imaging methods available, their most common indications, and certain principles concerning their use.

Since the late 1990s, there have been remarkable advancements in the effectiveness of cross-sectional imaging techniques for the diagnosis of thoracic diseases, particularly with the development of multislice *computed tomography* (CT), as well as improvements in *magnetic resonance imaging* (MRI) and ultrasonography. In many instances, cross-sectional methods have supplanted radiography for the diagnosis of chest diseases. As with any imaging method, the decision to utilize cross-sectional imaging should be based on consideration of the patient's clinical problem and the results of other imaging and laboratory testing.

Chest radiography still plays a fundamental role in the diagnosis of thoracic disease. Chest radiography is usually the initial imaging procedure performed when chest disease is suspected, and despite the proliferation of other imaging methods, chest radiography remains one of the most frequently performed radiographic examinations in the United States.

The thorax is difficult to image with radiographic techniques because of large regional differences in tissue density and thickness. For example, with standard radiography, the number of x-ray photons passing through the lungs is more than 100 times greater than the number of x-ray photons penetrating the mediastinum.¹ The dynamic contrast range of conventional film-screen radiography is insufficient to demonstrate this range of x-ray photon transmission properly; with standard radiographic techniques, the use of exposure high enough to display the mediastinum and the subdiaphragmatic regions usually results in overexposure of the lungs (Fig. 18-1A). Conversely, an exposure designed to provide the best visualization of the pulmonary parenchyma (see Fig. 18-1B) is normally too light to visualize mediastinal anatomy. One of the advantages of digital imaging is that displayed contrast and brightness are largely independent of the kilovoltage and milliamperage values used to obtain the examination; both contrast and brightness can be manually adjusted by the user after the image has been obtained.² Furthermore, the dynamic contrast range (latitude) of digital radiographic techniques exceeds that of film-screen methods by a factor of 10 or more.²

Chest radiography has been in use since the discovery of x-rays, and evolutionary developments in radiographic technology have addressed some of the fundamental limitations of radiographic techniques.¹ Whereas film-screen projection radiography was the primary method by which chest radiography was performed for many years, digital radiography has largely supplanted film-screen techniques, providing advantages such as image postprocessing and electronic storage of the radiographic data. The latter is particularly important because it allows for simultaneous

Figure 18-1 Overexposed versus properly exposed chest radiograph. **A**, Frontal chest radiograph performed with overexposed technique shows relatively good visualization of the mediastinum, but the lungs are abnormally “black,” which obscures fine detail. **B**, Repeat frontal chest radiograph performed with proper exposure shows slightly reduced ability to “see through” the mediastinum compared with the overexposed chest radiograph, but lung parenchymal detail is clearly superior in the properly exposed image. The proper exposure allows visualization of a left upper lobe nodule (arrow). (Courtesy Michael Gotway, MD.)

access to imaging studies by multiple providers and transmission of the data over long distances quickly.

Meticulous attention to technique is essential. Regardless of the method of recording the image, whether through standard film-screen radiography, image intensification, or digital recording, poor quality control leads to degradation of diagnostic information. Unfortunately, many technically inadequate radiographs are produced, leading either to repeat studies with additional patient radiation exposure or to interpretation of the poor images, increasing the chance of diagnostic errors.

Indications for the use of chest radiography are protean and include the assessment of both acute (e.g., pneumonia) and chronic (e.g., *chronic obstructive pulmonary disease* [COPD]) lung diseases, assessment of dyspnea or other respiratory symptoms, evaluation of treatment success for patients with acute lung disease, follow-up of patients with a known chronic lung disease, monitoring of patients in *intensive care units* (ICUs), diagnosis of pleural effusion, screening for asymptomatic diseases in patients at risk, monitoring patients with industrial exposure, preoperative evaluation of surgical patients, and as the initial imaging study in patients with known or suspected lung cancer and other tumors, vascular abnormalities, and hemoptysis. Abnormal radiographic findings can be quite subtle, however, and, in many circumstances the sensitivity and specificity of chest radiography is limited. In such situations, other imaging studies, especially chest CT, are performed to investigate abnormalities visible on radiographs or to evaluate patients considered high risk for a particular condition, but with normal chest radiographic results.

The utility of chest radiography has been studied in a number of clinical settings, and the appropriate criteria for their use have been determined by the *American College of Radiology* (ACR, <http://www.acr.org/Quality-Safety/Appropriateness-Criteria/Diagnostic/Thoracic-Imaging>). Although a detailed analysis of the diagnostic accuracy of chest radiographs in all instances is beyond the scope of this chapter, for illustrative purposes their utility and limitations in several specific clinical settings are reviewed.

CHEST RADIOGRAPHY: TECHNIQUES

RADIOGRAPHIC VIEWS AND TECHNIQUES

Routine Examination

A routine chest radiographic examination in an ambulatory patient usually consists of *posteroanterior* (PA) and left lateral projections. The utility of routine lateral radiographs, however, has been questioned. After analyzing more than 10,000 radiographic chest examinations obtained routinely in a hospital-based population, Sagel and associates²⁰ concluded that the lateral radiograph could be safely eliminated in the routine examination of patients 20 to 39 years of age. Conversely, they and others²¹ have concluded that the lateral radiograph should be obtained in patients with suspected chest disease and in screening examinations of patients 40 years of age or older (Fig. 18-2).

Expiratory Views

Conventional radiographs are made at total lung capacity (i.e., full inspiration), thereby permitting the greatest volume of lung to be evaluated for possible pathology and providing the most contrast between intrapulmonary air and normal and abnormal intrathoracic structures (Fig. 18-3). However, localized or generalized air trapping in the lung or pleural space is more easily detected (and sometimes only detected) on a radiograph made during expiration. The normal lung diminishes in volume and increases in density with expiration. Areas of trapping usually retain their lucency and volume regardless of the phase of respiration. With unilateral or localized air trapping, mediastinal shift (Fig. 18-4) and failure of normal elevation of the hemidiaphragm on the affected side are frequently apparent only on expiration. Small pneumothoraces, difficult to visualize and frequently overlooked on inspiratory radiographs, appear larger and more apparent on the expiratory study. As the thorax and underlying lung diminish in volume, the lung becomes denser, whereas the pneumothorax remains

The goal of chest radiography is to maximize diagnostic information through optimal film quality, while limiting radiation exposure to the patient. Although there are minor disagreements among experts, virtually all definitions of image quality include three general factors: radiographic contrast, resolution, and image noise.^{1,3} These are inter-related, and the ultimate quality of the radiograph is determined by the worst of the factors involved in its production.

MAJOR FACTORS AFFECTING IMAGE QUALITY IN STANDARD FILM-SCREEN RADIOGRAPHY AND DIGITAL RADIOGRAPHY

Standard analog film-screen radiography has been employed for the production of chest radiographic images for many years, but has largely been supplanted by digital techniques. With film-screen radiography, an x-ray photon is absorbed in a screen containing a photostimulable coating, resulting in the production of multiple light photons that, in turn, expose the actual film. This method differs from that used by digital radiographic techniques for image creation;⁴ the differences between film-screen and digital radiographic techniques are reviewed below. Nevertheless, the following discussion of technical factors impacting imaging quality applies to both methods.

Radiographic Contrast

Radiographic contrast, or *contrast resolution*, may be defined as the magnitude of signal difference between the imaged object and its surroundings in the displayed image,^{2,4} and it is principally determined by components of the system, chiefly the energy of the x-rays, and the degree to which secondary radiation (scatter) is eliminated. A film-screen combination possessing an intermediate or wide gray scale (latitude) is preferable to one producing extreme contrast^{1,3}; such “wide latitude” is intrinsic to digital radiographic production methods and, as will be discussed shortly, is one of the advantages digital imaging enjoys over older analog film-screen techniques. Although very “white-and-black” radiographs appear to demonstrate excellent detail, differentiation of structures differing slightly in density, such as the pulmonary vessels and the background lung, is better achieved with a wide-latitude film-screen combination or digital radiography. Wide-latitude film-screen combinations or digital radiography also better display the wide range of densities present in the thorax.¹

When an object is radiographed, some photons are absorbed or scattered, whereas others pass unaffected through the object (eFig. 18-1A). If the object is close to the detector, exposure from scattered radiation degrades image contrast and detail.^{1,3} Because production of scatter radiation varies with the volume of tissue being imaged, the use of devices, referred to as “collimators,” to restrict the beam size to the area being studied reduces scatter radiation. The further addition of filtration to the x-ray tube in the area of the collimator prevents low-kilovoltage radiation from reaching the patient, thus reducing the radiation absorbed by the patient without compromising diagnostic information.

Scattered radiation can also be removed by placing an antiscatter grid between the patient and the x-ray cassette

with film-screen systems (eFigs. 18-1B and 18-2A).^{1,3,5,6} Such grids permit the passage of the parallel primary x-ray photons to expose the detector while absorbing radiation scattered at an angle to the primary beam; the grid also absorbs some primary photons, making it necessary to increase the exposure technique to maintain the correct film density. Similarly, an exposure increase is also required when using grids with digital detectors to compensate for attenuation of the primary radiation beam by the grid.^{2,4} Care must be taken to ensure that the grid is of the proper type and is properly aligned to the x-ray beam. Placement off center, angulation, or the use of a grid focused at the wrong distance may affect the symmetry of radiograph exposure or even render it uninterpretable. Scatter radiation may also be reduced by increasing the distance between the detector and the patient, a process referred to as “creating an air gap” (eFigs. 18-1C and 18-2B). Some digital imaging systems, such as scanned-slot digital radiography detectors, have intrinsic scatter rejection capability and therefore do not require the use of a grid.^{2,4}

Spatial Resolution

Spatial resolution reflects the ability of an imaging system to allow two adjacent structures to be visualized as distinctly separate.^{2,4} Spatial resolution of film-screen combinations in common use is 10 to 12 line pairs/mm and is primarily determined by the thickness of the screen employed (thicker screens are associated with poorer spatial resolution).^{2,4} Other technical issues are responsible for limiting spatial resolution in digital radiography systems.^{2,4} A number of other factors may contribute to the reduction of the final resolution achieved on a chest radiograph produced by either film-screen or digital techniques. The use of large focal spots, particularly in thick body parts such as the thorax, degrades resolution by producing “edge unsharpness” or blur due to penumbra effects. Conversely, the limited capacity of a very small focal spot dictates a long x-ray exposure, and body motion can degrade spatial resolution, also causing edge unsharpness. A compromise choice in x-ray focal spot size of 1 mm or less is recommended. Lengthening of exposure duration causes degradation of spatial resolution because of insufficient power of the x-ray generator or deficiency of the heat capacity of the tube. Ideally, exposure duration should not exceed 25 msec and, for frontal projections, should be considerably less. A tube-detector distance of at least 6 feet (1.8 m) is usually used to reduce magnification and image blurring (see eFig. 18-2).

Noise

All imaging systems are limited by noise, which, in radiography, may be defined as fluctuations within the image that do not correspond to variations in x-ray attenuation in the imaged object.^{2,4} In radiography, noise is frequently referred to as “quantum mottle.”³ Noise is primarily determined by the number of x-ray photons used to produce the image, although factors intrinsic to the imaging systems contribute to image noise.^{2,4} The fewer the number of photons, the noisier the image will be. With a given film-screen or digital system, attempts to increase speed generally result in decreased resolution because of mottle.

X-ray screens that employ rare earth phosphors and have the property of converting x-ray photons to light more

efficiently have been developed. When used with properly matched films, these rare earth screens double or triple the speed at which a properly exposed radiograph can be made. They do not increase the noise of the system significantly and they permit reduction of radiation exposure to the patient by one half or more.

American College of Radiology Standards

The ACR standards for performing adult chest radiography (http://www.acr.org/~media/ACR/Documents/PGTS/guidelines/Chest_Radiography)⁷ specify the use of at least a 72-inch tube-film distance, a tube focal spot not to exceed 2 mm (0.6 to 1.2 mm recommended), rectangular collimation and beam filtration, a high-kilovoltage technique (120 to 150 kVp) appropriate to the characteristics of the film-screen combination, a film-screen speed of at least 200, an antiscatter technique (grid or air gap) equivalent to a 10:1 grid (preferably 12:1), and a maximum exposure time of 40 msec. The ACR also specifies a maximum mean skin entrance radiation dose (0.3 mGy/exposure). Guidelines for the production of digital chest radiographs have been published.²

Portable Radiography

The proliferation of ICUs and the increased use of patient monitoring for life-support devices have significantly increased the number of portable radiographs obtained.^{1,8,9} As indicated earlier, these examinations are necessary to determine whether catheters, endotracheal tubes, intra-aortic balloons, and various other devices have been correctly placed (eFigs. 18-3 to 18-7).^{10,11} Portable radiographs are also essential for assessing responses to therapy and for surveying for the presence of new thoracic disease.

Even under ideal circumstances, the quality of the radiographs obtained with portable techniques does not approach the standard of those made in the radiology department (eFig. 18-8). Portable examinations are generally made at a focal spot–detector distance of less than 72 inches, resulting in penumbral blurring, edge unsharpness, and degradation of fine detail.³ The routine use of the *anteroposterior* (AP) projection, with the recording device adjacent to the patient's back, magnifies the cardiac silhouette and other anterior structures. When possible, the radiograph should be obtained with the patient in the sitting position, but this is frequently not feasible. Images obtained with the patient recumbent compromise the detection of pleural effusions and pneumothorax, as well as the assessment of the gravitational distribution of pulmonary blood flow based on vessel size and lung zone opacity.

None of the several different types of mobile generators available is ideal. Exposure duration is difficult to control and is relatively long, and motion blurring degrades the image. Because of these limitations and the frequent need for immediate viewing of chest radiographs, storage phosphor-computed digital units are widely used for ICU radiography (see later discussion).¹¹ The storage plate phosphor's ability to provide relatively even density for overexposed and underexposed films and its ability to adjust the images digitally to visualize mediastinal or pulmonary parenchymal areas are well suited for ICU portable radiography.

The ACR standards for performance of portable chest radiographs (http://www.acr.org/~media/ACR/Documents/PGTS/guidelines/Portable_Chest.pdf) are relatively forgiving.^{7,12} A tube-film distance of 40 to 72 inches is recommended, closer to the latter preferred. From 70 to 100 kVp is recommended if a grid is not used, whereas more than 100 kVp may be used in conjunction with a grid. Exposure times should be as short as feasible to reduce motion artifacts.

Digital (Computed) Radiography

The development of reusable radiation detectors along with advances in electronics and computer technology enabled the development of a new type of radiographic imaging: digital radiography and computed radiography.^{1,13} These systems are fundamentally different from film-screen radiography in that image detection can be completely separated from the method of image display⁴ and, because the images are digital in format, they can be subjected to significant postprocessing to improve diagnostic information.⁴ Also, digital image receptors have a much wider range of sensitivity, or latitude, compared with standard film-screen combinations (10,000:1 rather than 100:1), and their response to radiation is linear over this entire range.^{1,2} Within these large limits, image contrast is independent of exposure. Furthermore, digital images can be displayed, transmitted, and stored electronically,^{2,3} and digital systems allow for faster patient throughput, increased dose efficiency, and possibly reduced x-ray exposure compared with film-screen techniques.^{4,13} These advantages have allowed digital radiography to supplant film-screen radiography in many radiology facilities.¹³

Storage Phosphor Systems

A commonly employed system of digital radiographic imaging, known as *computed radiography* (CR), uses imaging plates that are exposed by conventional radiographic equipment and can be used like any x-ray cassette.^{1,3} The reusable plates are coated with a photostimulatable phosphor that absorbs energy and retains a latent image when exposed to x-rays. The stored energy of the latent image is released as light when the plate is scanned by a laser in an image plate reader.⁴ The light produced is measured and digitized, yielding an image that can be subjected to contrast and spatial frequency enhancement and can be stored on magnetic or optical disks, viewed on monitors, or printed on film with a laser printer (eFig 18-9). The imaging plates are erased by exposure to light and may be reused almost immediately.

The resolution of digital images depends on the matrix size used. Spatial resolution is less than that of film-screen combinations (2.5 to 5 line pairs/mm), depending on the size and type of plate used to capture the image.¹ The unit can be set to perform automatic processing by preprogramming parameters for certain examinations or may be postprocessed manually by the radiologist to enhance various specific image features.¹⁴ The contrast scale can be altered, and the optical density of the entire image, or of various areas, can be changed. Edge enhancement can be obtained by amplifying high frequencies to visualize minute pulmonary detail. For the thorax, the automatic processing can be preset to produce a pair of images: one resembling a

conventional film-screen radiograph and the other exhibiting varying amounts of edge enhancement (eFig. 18-10).

An obvious advantage is that the images can be immediately transmitted electronically and viewed at a workstation in the emergency department, ICU, operating room, or other area where online viewing is required.^{1,3} Because the images are stored electronically, they may be recalled for comparison with subsequent studies, and they may be printed for conventional display at any time. High-resolution display units (2000-line) allow displayed images with excellent spatial resolution.

Clinical Efficacy

A large number of studies have compared digital imaging systems with conventional film-screen radiographs in both measured physical performance and interpretive accuracy. It is generally agreed that the denser portions of the thorax and the lung in front of or behind these dense areas are seen

significantly better with digital systems. There is disagreement concerning visualization of fine lung detail, line shadows, pneumothoraces, and interstitial lung disease.¹⁵⁻¹⁹ An important consideration is that digital recording systems have a very wide exposure latitude, and adequate images can be obtained with a wide range of exposures, which reduces the need for repeat imaging.⁴

Factors other than image quality have played a preeminent role in the dissemination of digital techniques. Among these are immediate availability of the images, ease of storage and retrieval, interaction with hospital electronic information systems, and cost of film and file room operation. CT, MRI, ultrasonography, and nuclear medicine studies already are digital. The completely digital imaging department is now common and will likely be ubiquitous in the near future. Digital imaging also enables the use of computer-aided detection techniques, particularly in the setting of mammography, chest radiography, and chest CT.¹

Figure 18-2 The utility of the lateral radiograph. **A**, The posteroanterior radiograph shows no specific abnormalities. **B**, The lateral radiograph identifies a mass (arrows) projected over the hilum. **C**, Axial chest CT confirms the presence of a mass (arrow) in the right lower lobe posterior to the bronchus intermedius (arrowhead). The lesion was found to represent bronchogenic carcinoma. (Courtesy Michael Gotway, MD.)

Figure 18-3 Comparison of radiographic appearances of thorax between expiratory and inspiratory radiographic techniques. **A**, Frontal chest radiograph performed with expiratory technique shows basal opacities (arrows) bilaterally. The mediastinum is wide, and the heart size is difficult to assess. **B**, Repeat frontal chest radiograph performed at full inspiratory volume made shortly following (**A**) now shows clearing of the basal opacities; the heart size is clearly normal and the mediastinum now shows normal width. (Courtesy Michael Gotway, MD.)

Figure 18-4 Unilateral hyperlucent lung in an 8-year-old boy with a foreign body in the right main-stem bronchus. **A**, The inspiration radiograph shows mild hyperlucency of the right lung. **B**, The expiration film shows that the right hemidiaphragm remains fixed in a low position, the right lung remains lucent, and the mediastinum is shifted to the left (air trapping). A foreign body was removed. (Courtesy Michael Gotway, MD.)

essentially unchanged in size, thus occupying a greater proportion of the deflated hemithorax, thereby being outlined more clearly by denser pulmonary parenchyma (Fig. 18-5).

Other causes of localized or unilateral lucency on the radiograph are differentiated from air trapping by the

expiratory study. Among these are technical causes such as patient rotation (eFig. 18-11), miscentered x-ray beam or grid, and “the anode-heel effect,” an artifact of asymmetrical generation by the anode of the x-ray tube. Chest wall abnormalities, either congenital or postsurgical (Fig. 18-6),

Figure 18-5 Inspiration and expiration chest radiography of pneumothorax. **A**, On the inspiratory image, the right pneumothorax is difficult to visualize but is faintly seen in the right upper thorax (arrows). **B**, On the expiratory image, the right pneumothorax (arrows) is outlined against denser lung and appears larger than on the inspiration (**A**) study. (Courtesy Michael Gotway, MD.)

Figure 18-6 “Unilateral hyperlucent lung” simulating air trapping. Frontal chest radiograph shows lucency throughout the left thorax compared with the right, simulating air trapping (compare with Fig. 18-4B). Note, however, that the left thorax shows neither abnormally increased (unlike Fig. 18-4B), nor decreased, lung volume. The left axillary surgical clips are a clue to the cause of left lung hyperlucency: left mastectomy for previous breast malignancy. The removal of left thoracic soft tissue creates less tissue density along the path of travel of the x-ray photons through the patient’s left side relative to the right, resulting in relative lucency of the left thorax compared with the right. (Courtesy Michael Gotway, MD.)

can produce unilateral lucency. Undetected areas of atelectasis with compensatory overexpansion of portions of the lung and primary vascular disease, such as pulmonary embolus (see eFigs. 57-7 and 57-9), may also produce lucency. None of these causes of pulmonary lucency will show trapped air on the expiratory radiograph.

Figure 18-7 The value of decubitus radiography. This patient had right pleuritic chest pain. **A**, A frontal chest radiograph shows no specific abnormalities; the right costophrenic angle is sharp. **B**, A right lateral decubitus radiograph shows a small right pleural effusion (arrows). Note that decubitus imaging causes collapse of the ipsilateral lung. (Courtesy Michael Gotway, MD.)

Decubitus Views

Decubitus radiography is performed by placing the patient in the recumbent position, usually lying on one side and then the other. The x-ray exposure is made with a horizontal beam in either the AP or PA projection.

The technique is useful for determining the presence or absence of free fluid in the pleural space or parenchymal cavities, for estimating the size of effusions, and for diagnosing pneumothorax in patients who are unable to sit or stand. Free fluid gravitates to the dependent portion of the thorax, which in the decubitus patient lies against the lateral rib cage of the dependent hemithorax (Fig. 18-7) or the mediastinum of the contralateral side; pneumothorax behaves in the opposite fashion. In the typical AP supine chest radiograph, free fluid will layer posteriorly and manifest as an increase in density involving the entire hemithorax. Air within the pleural space will collect anteriorly and is often difficult to detect. The proper use of decubitus

radiography will demonstrate the presence of free fluid, pneumothorax, or both (Figs. 18-8 and 18-9). When a portable study must be performed with the patient in bed, it may be technically difficult to obtain high-quality radiographs of the dependent portion of the hemithorax due to the underlying bed, clothes, or other inconveniences. For this reason, bilateral decubitus studies may be obtained. Even in patients in whom PA and lateral erect radiographs can be performed, subpulmonic effusions may be difficult to detect, and no fluid meniscus may be visualized. Unless the fluid is completely loculated, a decubitus study will demonstrate its presence and size (see Fig. 18-9). As little as 20 mL of fluid can be seen in the decubitus position.

Lordotic Views

Radiographs made in the lordotic position can be of value in demonstrating lesions in the immediate subclavicular region or partially hidden by the clavicle (eFig. 18-12). This is particularly true if these lesions are located posteriorly. In the lordotic view, which is most frequently obtained in the AP projection, the clavicle, being an anterior structure, is projected above the lung apex, and the subclavicular lung regions are well visualized (see eFig. 18-12). The lordotic view may also be used to confirm middle lobe or lingular atelectasis. A lordotic view centered over the lower portion of the chest will project the atelectatic lobe or segment so

Figure 18-8 Comparison of pneumothorax appearance at upright and lateral decubitus chest radiography. **A**, Upright inspiratory frontal chest radiograph shows the typical appearance of a pleural line (arrows) over the apex of the right lung, representing pneumothorax. **B**, Left lateral decubitus chest radiograph shows the gas in the pleural space has migrated in a nondependent fashion over the entire peripheral right thorax, creating a pleural line (arrows) over both the apical and costophrenic regions. (Courtesy Michael Gotway, MD.)

Figure 18-9 The value of decubitus radiography in a patient with right thoracic pain. **A**, Frontal chest radiograph shows apparent elevation of the right hemidiaphragm, but the right costophrenic angle is sharp. **B**, Lateral chest radiograph reveals obscuration of the posterior portion of the right hemidiaphragm, but a clear meniscus indicating right pleural effusion is not seen. **C**, Right lateral decubitus radiograph reveals the presence of a large, free pleural effusion (arrows). The apparent elevation of the hemidiaphragm on the conventional posteroanterior and lateral radiographs is due to subpulmonic effusion. (Courtesy Michael Gotway, MD.)

that it directly faces the x-ray beam, and it will be easily visualized as a dense triangular shadow.

Oblique Views

Occasionally, shallow oblique views are valuable in sorting out superimposed shadows and in visualizing pulmonary parenchymal opacities obscured by superimposition from the heart, mediastinum (eFig. 18-13), or portions of the bony thorax. In general, it is more rewarding to study these opacities with CT.

FLUOROSCOPY

Fluoroscopy at one time was commonly employed either as the primary method of radiologic examination of the chest or as an adjunct study to standard radiographs. Its use over the past several decades has diminished considerably. However, there remain a few situations in which fluoroscopy can provide information that is difficult to obtain by other means, such as for the detection of abnormalities of diaphragmatic motion that result from conditions affecting the phrenic nerve (Video 18-1). The major use of chest fluoroscopy in current medical practice is as a guide for interventional procedures such as catheter angiography and needle or transbronchial biopsies.

An expanded discussion of different radiographic modalities and technique is available online at ExpertConsult.

COMPUTED TOMOGRAPHY

PHYSICAL PRINCIPLES

CT is based on the precise measurement of attenuation of a thinly collimated x-ray beam. Differential x-ray beam attenuation by different tissues forms the basis of image contrast on CT images. The advantages of CT are its axial tomographic (“slicelike”) format and its high sensitivity to differences in density between different tissues.

To obtain CT images, x-rays—produced by a modified standard x-ray tube—are passed through the patient, and the transmitted photons are measured by a series of x-ray detectors. The detectors produce an electric current that is proportional to the intensity of the incident x-ray beam. The strength of this current is measured and digitized by an analog-to-digital converter and thus is available for computer manipulation. The reduction in the intensity of the beam as it passes through the patient’s body is termed “attenuation” and is due to scattering and absorption of the x-ray photons by tissue. The attenuation (more precisely, the linear attenuation coefficient) of each point within the body can be calculated by the scanner’s computer, provided that multiple measurements of x-ray attenuation can be made from different angles. The details of the x-ray beam and detector motion by which these multiple measurements are obtained vary considerably among scanners.

Spiral, or helical, CT scanners, and more recently, multislice CT scanners, use a continuously rotating gantry (containing the tube and detector array) and are capable of imaging the entire thorax in a single breath-hold.

Because the x-ray attenuation measurements are stored in the computer, the image can be enhanced or manipu-

lated mathematically with specific reconstruction algorithms. For example, the technique of *high resolution CT* (HRCT) combines narrow collimation and image reconstruction with a high-spatial-frequency algorithm to produce increased sharpness in the final stage.

IMAGE DISPLAY

The reconstructed CT image is made up of a matrix of picture elements or “pixels.” The x-ray attenuation of each pixel is normalized to that of a test object containing pure water. The CT number is the ratio of tissue attenuation minus water attenuation relative to water attenuation multiplied by 1000 and is expressed in *Hounsfield units* (HU). The CT number for normal lung ranges from −700 to −900 HU, whereas soft tissues have CT numbers ranging from −100 (fat) to +100 HU (blood clot), with water measuring 0 HU and most soft tissues in the 20 to 60 HU range. The range of CT numbers encountered in patients is approximately 2000, ranging from −1000 (air) to +1000 (bone). However, although the computed image contains 2000 number levels, which could correspond to 2000 shades of gray, the human eye can perceive only about 16 to 20 distinct shades of gray. It is thus necessary when displaying CT images to restrict the image display to a small fraction of the actual range of attenuation values.

This restriction is done first by combining similar CT numbers into a single gray shade and second by setting the window width and window level display settings. The window *width* is the range of densities that will be displayed as shades of gray; all higher pixel values are shown as white, and all lower ones are shown as black. The window *level* is simply the median pixel value about which the display range is centered. Thus, to view the lungs, an appropriate window level is −700 HU, with a window width of approximately 1200 HU, which may be adjusted depending on user preference. For viewing soft tissues, pleural space, mediastinum, or hila, a window level of 20 to 40 HU with a width of approximately 400 HU is preferred. These are usually referred to, respectively, as “lung window” and “mediastinal or soft-tissue window” settings, and both should be displayed for a chest CT study.

SPIRAL AND MULTISLICE COMPUTED TOMOGRAPHY

The terms “spiral” and “helical” CT are essentially equivalent; they refer to the path the rotating x-ray beam describes as a result of its continuous rotation around the longitudinal axis of the patient as the patient is transported through the CT gantry on a continuously moving table. In many patients, the entire thorax can be scanned during a single breath-hold. Spiral CT has the advantages of (1) volumetric imaging, which ensures contiguous image reconstruction and allows multiplanar or three-dimensional reconstructions to be performed; (2) more rapid scanning; and (3) more rapid contrast infusion with denser opacification of vessels.

Volumetric CT refers to the ability of modern CT scanners to acquire scan data continuously between two points (in the thorax, typically from the cervico-thoracic junction to the diaphragm), rather than, as with older CT technology,

BRONCHOGRAPHY

Contrast bronchography, formerly a fairly common thoracic examination, has been replaced by fiberoptic bronchoscopy and either CT or *high-resolution computed tomography* (HRCT) of the lung. In patients with suspected bronchiectasis, HRCT and CT are as sensitive and are safer, more easily obtained, and much more pleasant to undergo than bronchography.

PULMONARY ANGIOGRAPHY

Pulmonary angiography has traditionally been employed primarily for the detection or exclusion of pulmonary embolism (eFig. 18-14; see Figs. 57-7, 11, and 16, **Video 18-2**). Although it has been traditionally regarded as the “gold standard” for making the diagnosis of pulmonary embolism, it has limitations and tends to be underutilized.²² Other situations in which pulmonary angiography has been employed include the diagnosis and embolization of pulmonary arteriovenous malformations (eFig. 18-15; see Fig. 19-14; and Chapter 61), pulmonary arterial foreign body retrieval, pulmonary vasculitis (eFig. 18-16; see Chapter 60), and occasionally, the delineation of the anatomy of pulmonary vessels before lung surgery. The study is performed by rapidly injecting intravenous contrast material through a catheter and imaging the lung while the contrast material traverses the arteries and veins. Most frequently, the catheter is inserted into the femoral vein percutaneously and then guided into the pulmonary artery under fluoroscopic control.

Angiograms may be done with the catheter in a main branch of the pulmonary artery or more selectively in distal vessels. The radiographic contrast material is injected at the rate of approximately 10 to 25 mL/sec, depending on the vessel size. The volume of contrast depends on the location of the catheter. Between 40 and 60 mL of contrast material is usually injected into the right or left main pulmonary artery; half this amount of contrast is needed with digital subtraction techniques. Selective injections made within the more distal pulmonary arteries require smaller volumes. If the angiogram is performed for the detection or exclusion of pulmonary embolism after an abnormal but nondiagnostic perfusion scan, the location of the perfusion defect on the scan may act as a “road map” for the angiographer, and selective or superselective injections proximal to the area of perfusion deficit may be performed.

Unless the angiogram is done with a balloon occlusion technique, serial recording is necessary. In the past, rapid film changers were used with an exposure rate of 3 or 4/sec, but such “cut-film” techniques have been replaced by digital subtraction angiography. Filming is usually carried out for several seconds after injection to permit visualization of the pulmonary veins, the left side of the heart, and the thoracic aorta.

It is frequently necessary to image in several different projections to confirm or exclude pulmonary embolism. Oblique or lateral projections may be desirable. If the angiographic suite contains biplane equipment, the number of necessary contrast material injections can be diminished by imaging in two orthogonal planes after a single injection of contrast medium. Magnification angiography may show

emboli in vessels that are too small to be seen clearly on standard studies.

For a definite diagnosis of pulmonary embolism, it is necessary to visualize the embolus as either a filling defect (see eFig. 18-14) within a vessel or the trailing edge of a thrombus. Other abnormalities should not be regarded as diagnostic of embolism.

Complications and death are rare, fortunately. Significant complications are seen in less than 5% of patients, and 0.1% to 0.5% of patients die undergoing angiographic studies to evaluate suspected pulmonary embolism.²³ Minor arrhythmias are not infrequent when the catheter tip traverses the right ventricle. Ventricular fibrillation has been reported, as has refractory shock. Electrocardiographic monitoring and immediate availability of defibrillating equipment are mandatory. Reactions to contrast material are most frequently minor and primarily consist of urticaria and vasovagal responses. However, patients can occasionally suffer major reactions, with bronchospasm and cardiopulmonary collapse. Renal failure after administration of iodinated contrast material is a well-recognized complication, and preexisting renal disease manifested by elevated serum creatinine levels represents a relative contraindication to angiography. In all circumstances, the amount of contrast material injected should be the minimum required to produce diagnostic opacification of the pulmonary vessels. The use of nonionic or low-osmolar contrast material diminishes the number of minor reactions and increases patient comfort during the procedure. It is now routine in most practices.

AORTOGRAPHY AND BRONCHIAL ANGIOGRAPHY

Aortography is generally accomplished by the retrograde passage of a catheter from the femoral artery to the aorta or its branches after percutaneous insertion (eFig. 18-17). The study of the aorta and its branches plays a limited role in diseases of the lung. The imaging modalities of choice for diagnosing suspected aortic abnormalities, including aortic dissection, are CT, MRI, and, in acute cases, transesophageal ultrasonography; aortography is seldom required. The diagnosis of pulmonary sequestration once depended on the demonstration of anomalous systemic blood supply by aortography but, in modern practice, chest CT aortography and *magnetic resonance angiography* (MRA) are often diagnostic and easily demonstrate the abnormal vascular supply (eFig. 18-18). Patients with severe hemoptysis may require bronchial arteriography and embolization of the bronchial artery or arteries supplying the bleeding site (eFig. 18-19). These studies require selective catheterization of the bronchial arteries. Angiographic technique is, for the most part, individualized to fit the particular clinical condition being studied.

Angiography can be performed with a technique termed “digital subtraction angiography.” With digital subtraction angiography, an early image from the angiogram is recorded with an image intensifier and a high-resolution television camera and is digitized and stored. A later image in which vessels are opacified is handled in a similar manner. The first image is then subtracted from the second, and the resulting image is displayed. The background body structures are

subtracted, leaving an image of the contrast-filled vessel (see [eFigs. 18-17](#) and [18-19](#)). Because the body background does not obscure the final image, angiography can be accomplished with smaller amounts of contrast than otherwise necessary. Motion of structures in the area being studied may make subtraction of images difficult.

ULTRASONOGRAPHY

Ultrasonography, which is also discussed in Chapter 20, has limited usefulness in thoracic imaging because the ultrasound beam is reflected at the air-soft-tissue interface around the lungs, but some specific uses have been recognized.²⁴⁻²⁶ It is useful for studying vascular, cardiac, and some mediastinal abnormalities, for the localization of pleural fluid and air collections, and for directing interventions (see Fig. 19-3). Transesophageal sonography can allow imaging of some mediastinal structures and is often performed to assess the thoracic aorta and heart. The use of ultrasonography in lung imaging is largely limited to the pleura and immediate subpleural areas or to areas of consolidated lung or masses contacting (see Fig. 19-3) or invading the chest wall. It is most commonly utilized for the detection, localization, and characterization of pleural effusions and to guide thoracentesis ([eFig. 18-20](#)).

Ultrasonography is also valuable in differentiating effusion from pleural thickening. Effusion is usually anechoic or hypoechoic, whereas pleural thickening results in an echogenic stripe within the enclosing rib margin. When free-flowing or layering fluid is not demonstrated on decubitus radiographs in the presence of a thickened pleural stripe, ultrasound study may show collections of loculated

fluid surrounded by pleural adhesions. Septations may be visualized within pleural collections, and their shape may change during the breathing cycle, confirming the presence of low-viscosity fluid. A complex echogenic fluid collection indicates the presence of exudate, empyema, or hemothorax, but an echo-free collection does not exclude these diagnoses. Ultrasound is also effective in differentiating subphrenic fluid from pleural effusion because the two hemidiaphragms are excellent reflectors of the ultrasound beam and therefore provide a visible boundary distinguishing intrathoracic from subdiaphragmatic spaces ([eFig. 18-21](#)). The presence of a hypoechoic area caudal to the echogenic diaphragmatic stripe but cranial to the liver or spleen indicates ascites.

Ultrasound-guided thoracentesis is frequently performed when loculated fluid is suspected or after attempts at thoracentesis have failed.²⁷ The use of real-time equipment permits the performance of this procedure at the bedside (see [eFig. 18-20](#)). After locating the apparent fluid collection, the appropriate depth to which the needle should be inserted is displayed on the screen, and the aspiration is performed in the usual manner. Placement of catheters for drainage can be accomplished in a similar fashion.

Pleural neoplasms, mediastinal masses, or parenchymal masses that abut the pleural surface may be biopsied under ultrasonic guidance (see Fig. 19-3), provided that no aerated lung intervenes between the lesion and the pleura. The tip of the needle can be guided and identified within the mass, thus confirming appropriate placement before aspiration or biopsy.²⁸ However, CT (see Figs. 19-1, 2, and 6) or fluoroscopic guidance is more frequently employed for this purpose.

using a “stop-and-shoot” method. With the latter technique, individual image “slices” could be summed to create a volume of imaged tissue but were limited by misregistration between the individual image slices, particularly between successive individual breathholds. Owing to the rapid acquisition times of modern CT scanners, the entire thorax can now be imaged completely in a *single breathhold*, leading to a single “block” of tissue data that can be reconstructed into practically any desired slice thickness and imaging plane desired.

Multislice CT (MSCT) markedly improves on the advantages offered by single-slice spiral CT. MSCT scanners acquire information using *multiple channels* during a single tube rotation, thereby dramatically increasing the data acquisition rate. Current MSCT scanners may acquire up to 320 images per tube rotation for a given collimation, whereas routine single-slice spiral CT scanners would only acquire 1 image per tube rotation for a similar collimation. The speed advantage of MSCT scanning is obvious, and this tremendous speed allows for rapid imaging of large volumes of tissue in practically any phase of intravenous contrast enhancement. The image data sets provided by MSCT scanners also allow for improved-quality reformatted images (eFig. 18-22, Videos 18-3 and 18-4). Furthermore, the imaging data acquired with MSCT scanning allow for “retrospective reconstruction” of narrow section images (e.g., “thin sections” or “high-resolution” images) following scan completion.

With MSCT, the ability to reconstruct narrow section images retrospectively has transformed the process of nodule characterization. In the era of single-slice CT scanning, when narrow section imaging was used to characterize a pulmonary nodule, particularly by the detection of calcium or fat within the nodule, either the patient would

be held within the department and the radiologist contacted to review the scan to determine if narrow section imaging was required (with the associated detrimental effect on departmental throughput), or the patient would be called back at a later time for further imaging (with the associated patient and referring physician inconvenience). With MSCT scanning, CT protocols that acquire narrow sections (often on the order of 1 mm or less) are devised but are reconstructed using wider sections (often 5 mm) for routine interpretation, which allows for optimized computer performance and data handling; however, the narrow sections have been acquired and are available for review, if needed. In the foregoing example, if narrow sections are needed for pulmonary nodule characterization, the narrow section data may be retrospectively reconstructed and reviewed (Fig. 18-10). In fact, many radiology departments prospectively reconstruct both wider section widths for routine viewing and narrow section widths for specialized applications and save both series to the picture archiving communication system; such an approach strikes an excellent balance between the need for smaller data sets to facilitate routine data handling, while still allowing for specific questions to be addressed later through the use of thin-section imaging without reimaging the patient.

COMPUTED TOMOGRAPHY SCAN PROTOCOLS

CT scans are obtained with different parameters, depending on the indication for the examination (Table 18-1). Variables include scanning range, patient position, scan section thickness, table transport speed/pitch, and intravenous contrast injection rate, timing, and volume. These parameters are briefly reviewed later. The influence of table transport speed/pitch on CT protocols has evolved with the

Figure 18-10 Volumetric multislice CT imaging of a pulmonary nodule detected at chest radiography. **A**, “Routine” axial 5-mm CT image shows a soft-tissue nodule in the left upper lobe. Vaguely increased attenuation is seen within the nodule, suggesting calcification, but the finding is not well seen. **B**, Lung window images show that the nodule is circumscribed. **C**, Retrospectively reconstructed thin-section (1-mm) soft-tissue image more clearly shows a small focus of calcification (arrow) within the lesion, suggesting a benign etiology. (Courtesy Michael Gotway, MD.)

Table 18-1 Common Chest CT Scanning Protocols and Indications

Scan Protocol	Intravenous (IV) Contrast Use?	Common Indications	Notes
"Routine" chest CT* (including spiral and multislice technology)	Possibly, depending on specific application	Initial and repeat cancer staging (may be performed with IV contrast, depending on tumor type), nonspecific chest pain, cough, or shortness of breath, pleural disease, mediastinal or chest wall mass evaluation, suspected thoracic lymphadenopathy, investigation of focal chest radiographic abnormalities, suspected infection, lung cancer screening	IV contrast injection often beneficial for suspected lymphadenopathy, pleural disease, bronchogenic malignancy staging. Employed for fever of unknown origin (often when chest radiography is unrevealing, particularly for immunosuppressed patients). Often used for evaluation before solid or hollow organ transplant to assess for asymptomatic findings that could represent malignancy. Aggressive radiation dose reduction frequently employed for lung cancer screening studies
CT pulmonary angiography	Yes	Assessment of suspected acute or chronic thromboembolic disease, pulmonary artery aneurysm, or pulmonary artery anomaly	IV contrast injection timing scaled for optimal pulmonary artery enhancement
CT aortography	Yes	Assessment of suspected aortic dissection or aneurysm	IV contrast injection timing scaled for optimal aortic enhancement
Coronary calcium scoring	No	Evaluation for presence of calcified coronary artery atherosclerosis for heart disease risk stratification	Volume of acquisition limited to heart
Coronary CT angiography	Yes	Evaluation for coronary artery atherosclerosis, aneurysm, or anomaly	Scan performed with ECG gating for motion-free images. Volume of acquisition typically limited to heart
Cardiac CT	Yes	Evaluation for congenital or acquired structural cardiac disease, pericardial disease, or assessment of specific mediastinal or lung pathology impact on heart	Scan performed with ECG gating for motion-free images. Volume of acquisition typically extended slightly beyond heart to include great vessel anatomy. Contrast injection timing may be adjusted to suit particular indications
Pulmonary vein CT	Yes	Assessment for pulmonary venous and left atrial anatomy before electrophysiologic ablation	Contrast injection timing optimized for left heart enhancement
High-resolution CT	Typically not required, although in the case of initial evaluation of suspected sarcoidosis, may be of benefit	Diffuse lung disease at chest radiography or suspected by clinical evaluation—initial diagnostic assessment, biopsy site selection, serial evaluation of treatment efficacy; small airway diseases, bronchiectasis, chronic dyspnea or progressive exercise intolerance, assessment of abnormal pulmonary functions testing, lung transplantation evaluation	Thin-section imaging with prone and postexpiratory imaging as well
Contrast-enhanced chest CT for solitary nodule evaluation	Yes	Evaluation of an indeterminate solitary pulmonary nodule (typically > 1 cm, <3 cm)	Specific, weight-based contrast injection protocol with structured timing of image acquisition to assess for nodule enhancement. Lack of nodule enhancement strongly suggests an indeterminate nodule is benign

*"Routine" chest CT section thickness (collimation) varies depending on scanner manufacturer, but typically approximates 5 mm. Narrower sections are routinely automatically obtained with modern multislice CT scanning protocols (on the order of ≤ 1 mm); however, these images may or may not be reconstructed and archived in the picture archive and communications system (PACS), depending on individual radiology departmental protocols. Even when such images are routinely reconstructed and archived to PACS, often an additional series of images employing a wider reconstruction interval (typically approximately 5 mm) is saved to PACS to facilitate day-to-day interpretation and data handling and storage efficiency.

ECG, electrocardiogram.

proliferation of MSCT scanners. Consideration of these variables is more relevant to cardiovascular imaging and is not discussed here. The interested reader is referred to excellent reviews on the topic of MSCT scan parameters and the technical aspects of MSCT scanning.^{22,23} Owing to MSCT's rapid scan capability and ability to retrospectively reconstruct narrow section data, in recent years there has been some degree of CT protocol "simplification" compared with the single-slice CT era. For example, single-slice high-resolution CT protocols previously included noncontiguous supine and prone 1-mm inspiratory scans, as well as noncontiguous supine expiratory scanning. Using such a protocol, it was not uncommon to mistake a pulmonary vessel for a lung nodule; the inability to review adjacent sections immediately cranial and caudal to the vessel, owing to the noncontiguous nature of single-slice high-resolution CT protocols, often resulted in a pulmonary vessel simulating a nodule. This high-resolution CT protocol was distinct from the "routine" single-slice CT chest protocol, employing contiguous imaging, that was required to clarify the nature of this potential abnormality. Current MSCT high-resolution CT protocols, however, employ contiguous 1-mm supine imaging routinely, supplemented with noncontiguous 1-mm prone inspiratory and supine expiratory imaging, thus alleviating the difficulties associated with noncontiguous imaging techniques while simultaneously maintaining the benefits of thin-section imaging in the characterization of diffuse lung diseases.

Scanning Range

In most instances, a chest CT study should encompass the entire thorax, from the lung apices to the posterior costophrenic angles. This is easily accomplished in a matter of a few seconds with MSCT. In patients with lung cancer, chest CT done for staging purposes may include the adrenal glands and liver, although the liver acquisition should be timed properly to obtain images in the correct phase of liver enhancement. In practice, lung cancer staging studies are typically performed as dedicated examinations of the entire chest, abdomen, and pelvis.

Patient Position

Normally, patients are scanned in the supine position. However, decubitus positioning or prone positioning may be used to elucidate whether pleural fluid collections are free or loculated, to distinguish dependent atelectasis from parenchymal fibrosis, or to position lung lesions optimally for biopsy. Images are normally obtained at total lung capacity to obtain maximum air-tissue contrast and to spread anatomic structures and lesions over a larger area, thus minimizing volume averaging. Prone images are usually obtained with HRCT studies. Technical advances now permit the acquisition of CT images during, rather than after, forced expiratory vital capacity maneuvers (see  [Videos 106-1 to 3](#)).

Scan Section Thickness

In the era of single-slice spiral CT, the thickness of an individual CT section was set to a predetermined value before scanning by setting the x-ray beam to a certain thickness: a process referred to as "collimation." Typical slice thicknesses for single-slice spiral CT ranged from 1 to 10 mm,

with 5- to 7-mm collimation employed for most "routine" chest CT applications. With the development of MSCT systems, although various collimation choices are still possible, most MSCT protocols employ certain detector configurations that either favor narrow detector width (to promote optimal spatial resolution) or wider detector widths (to facilitate rapid volume of coverage). As systems with greater numbers of detectors are developed, the choice of high spatial resolution at the expense of volume of coverage and total length of exposure—an age-old compromise in the era of single-slice spiral CT—is becoming less of a quandary. Modern MSCT systems now allow the entire thorax to be scanned with a narrow detector configuration (1 mm) in a matter of a few seconds. Once such images are acquired, they may be combined in various ways for optimal viewing. For example, a chest CT study obtained on an MSCT system with detector elements arranged in a manner resulting in 1-mm detector configuration would produce several hundred 1-mm images for the thorax of an averaged-sized patient. However, these 1-mm images can be "combined" to generate 5-mm images, and these images can be displayed for routine review; this results in about 50 to 70 images for a typical chest CT. Should the radiologist desire to view the high-resolution, 1-mm images, these images can be reconstructed from the original dataset as long as the original scan data are saved. For example, with single-slice spiral CT scanners, frequently the patient would need to return for additional thin-section (narrow-collimation) imaging to characterize any nodules encountered at the examination. The only way to avoid bringing patients back in this setting was to keep the patient on the scanner while the study was reviewed, but this approach seriously decreases scanner throughput. Even if the patient were held during the scan review, additional nodule characterization with single-slice CT would require repeat scanning with narrow collimation to detect fat or calcium within the nodule, which requires additional radiation exposure. With MSCT, when a nodule is recognized on a study, images may be reconstructed according to the narrowest detector configuration to accomplish this goal long after the patient has left the scanner, without the need for additional scanning.

An additional benefit realized by the development of MSCT is the ability to image using isotropic voxels. The term *isotropic voxel* indicates that the resolution of the scan in the x-, y-, and z-planes is equal. In other words, MSCT scanning using isotropic voxels allows the CT data to be reconstructed in any plane with resolution equal to that of the axial scans. Most single-slice CT examinations did not possess this capability, and therefore nonaxial reformatted images suffered from degraded quality compared with that of the axial scans. MSCT's ability to scan using isotropic voxels allows creation of images in any desired plane that are equal in resolution to the axial scans (see [eFig. 18-22](#), [Videos 18-3](#) and [18-4](#))—this multiplanar capability was previously an advantage enjoyed by MRI and ultrasound over CT. 

Contrast Enhancement

The injection of intravenous iodinated contrast material during chest CT is important in many situations. Administration of contrast material is not routine except for the diagnosis of vascular abnormalities such as aortic dissection, aneurysm, pulmonary embolism, when using

a specific protocol in selected patients with pulmonary nodules, or for examinations performed for lung cancer staging or assessment of pleural or chest wall diseases. If possible, iodinated contrast materials are avoided because they are expensive and associated with a small but definite risk of serious reactions and toxicity. Although contrast infusion can be helpful in distinguishing vessels and soft-tissue masses in the mediastinum and hila, it is not considered necessary for diagnosis by all radiologists. For routine CT of the lungs (e.g., to rule out metastases), contrast material is rarely required.

Nonionic and low-osmolar contrast materials have proved to have a lower incidence of adverse reactions than high-osmolar agents.²⁴ Patients with a prior history of contrast reaction should be treated with extreme care because they are at higher risk for subsequent serious reactions, particularly those rare patients that have experienced contrast reactions despite proper premedication with corticosteroids and antihistamines.^{24,25} If vascular pathology is of interest in such patients, MRI is the preferred modality. If CT with contrast enhancement is necessary, pretreatment with corticosteroids is advisable. Iodinated contrast media reactions (“radiographic contrast-medium-induced leukostasis”) is discussed in Chapter 71.

The technique of intravenous contrast material administration is important. Peak opacification of vascular structures is desirable. To achieve this, a bolus of contrast material must be administered, preferably via a calibrated mechanical injector, and the area of interest must be scanned rapidly during the initial transit of the contrast agent. Timing of the delivery of intravenous contrast should be adjusted to the organ system of interest. For example, chest CT protocols designed for the detection of pulmonary embolism generally use rather short delays from the time of the beginning of contrast injection to the start of imaging (usually ≤ 20 sec), whereas chest CT protocols designed for the evaluation of aortic dissection generally use slightly longer contrast injection delays.

MEDICAL IMAGING AND RADIATION

The major drawback of the increased utilization of CT is radiation exposure. In 1980–1982, radiation from medical imaging accounted for approximately 18% of the per-capita effective radiation dose in the United States, but this value increased to 54% by 2006, due largely to increased radiation doses resulting from CT scanning and, to a much lesser extent, nuclear medicine procedures. It was recently reported that CT represents about 17% of all radiologic procedures in the world but accounts for more than 40% of the collective dose.³² Given the continued increased use of CT since 2006, it is likely that these numbers are now even greater.²⁶

Additional material regarding radiation exposure from medical sources is available online.

Approximate effective doses (scanner outputs) for CT are given in Table 18-2 and compared with nonmedical radiation exposures.²⁹ Of note, the values given are representative measurements but, in fact, there is a wide range of exposures dependent on CT technique and method of estimation. Also, indications such as pulmonary embolism, which require narrower sections, may involve a relatively

Table 18-2 Typical Radiation Doses Associated with Background Sources and Common Thoracic Imaging Applications and Environmental Exposures

Radiation Exposure	Effective Dose (mSv)
U.S. annual per-capita effective radiation dose 2006 (background/medical/total)	2.4/3.0/5.6 ³²
Posteroanterior chest radiograph*	0.02 ²⁹⁸
Ventilation/perfusion scan*	1.4–2 ^{298,299}
Standard chest CT	5–8 ^{298,299}
“Low-dose” chest CT	2
High-resolution chest CT (1-cm noncontiguous intervals)*	1
Catheter pulmonary angiography*	2.3–4.1
Whole-body PET*	14 ²⁹⁹
Coast-to-coast U.S. flight (≈ 3000 miles)†	0.03
Living near coal-fired power plant†	0.0003
Proximity to x-ray luggage inspectors	0.00002
Living within 50 miles of a nuclear power plant†	0.00009
Living in Denver for 1 year	1.8
Airport backscatter device	0.000015–0.00088 ³⁰⁰
Smoking, 1 year‡	2.8

*Values may vary according to individual equipment manufacturers, patient size, duration of study, use of dose-reduction techniques, and individual institutional protocols.

greater amount of radiation exposure compared with “standard” chest CT protocols. In recent years, concerted efforts to curtail medical radiation exposure have resulted in a number of advances that have significantly reduced the amount of radiation delivered to the patient, chiefly through reduction of CT-related exposures. A thorough review of these methods is beyond the scope of this brief discussion but includes increasing public and provider awareness through efforts such as the “ImageGently” campaign conducted by the Alliance for Radiation in Safety in Pediatric Imaging and the ACR’s “ImageWise” (radiation safety in adult medical imaging) effort; technical advances in CT scanner equipment (new reconstruction algorithms and automated exposure controls that more efficiently apply the radiation exposure to the patient, such as automatically reducing tube current through thinner body regions); encouraging the use nonionizing radiation imaging alternatives for selected disorders; and active interventions by radiologists, including limiting scanning range and reducing x-ray tube current and voltage, among other considerations. It is now relatively commonplace that exposures associated with newer CT protocols are significantly less than the values reported in Table 18-2 (Video 18-5).

Considerable controversy regarding the genesis and magnitude of adverse effects resulting from radiation exposure in humans exists and has been the subject of debate for decades.²⁷ The rapid rise in the use of CT scanning in recent

The two primary terms for describing the radiation imparted by a CT scan are *adsorbed* and *effective dose*. The adsorbed dose, measured in *grays* (Gy), is the energy absorbed per unit mass of a specific organ. In other words, it is the radiation imparted to a specific organ and thus accounts for the future risk of developing a malignancy at that site. Effective dose, measured in *sieverts* (Sv), is an overall estimate of total-body radiation exposure; this unit attempts to provide a measure of the overall potential harm caused by radiation exposure. Effective dose is defined as the radiation dose that must be delivered to the whole body to yield the same biologic consequences (specific for cancer induction only) as the dose actually received by the exposed organs.²⁷ This is calculated by summing the individual adsorbed doses to each organ, each of which is multiplied by a weighting factor reflecting individual organ radiosensitivities. Effective dose is useful for gross comparisons between different modalities and techniques. It should be understood that effective dose is *not* an actual measure of the radiation imparted to a patient during a given CT examination, although many published articles use this unit (often expressed as *millisieverts* [mSv] or in the form of the older unit, *millirems* [mrem]) in this fashion.²⁸ This miscon-

ception is compounded by the recording of a “patient dose report” as part of the CT scan report (eFig. 18-23). Rather, the actual radiation dose imparted to a patient during a CT examination depends directly on the size and shape of the actual patient.²⁸ The units reported by the CT scanner, often the *CT Dose Index* (usually expressed as the $CTDI_{vol}$, reported as an absorbed dose, in mGy) or the *Dose-Length Product* (DLP, reported as an effective dose, in mSv, and equal to the $CTDI_{vol}$ multiplied by the irradiated scan length), are measures of *scanner radiation output*, not patient dose. Calculating the radiation dose imparted to a patient during a given CT scan requires complex equations that take into account patient size, shape, body composition, and the organs irradiated, as well as scanning range. With knowledge of the patient size, body region scanned, CT scanner output, and scan length, a reasonable approximation of patient dose for a given CT scan is possible, but it remains imperative to understand that the units of scanner output—the CTDI and DLP—are not measures of patient radiation dose.²⁸ Therefore, these parameters should not be used to estimate potential cancer risk or radiation-related deterministic effects (e.g., skin injury) for individual patients undergoing medical imaging procedures.²⁸

years, as well as several well-publicized patient overexposure events at CT scanning, have fueled this debate.²⁷ Nevertheless, several points can be agreed on by investigators on both sides of this debate:

1. Radiation is potentially harmful to biologic systems and exposure can induce cancer, among its other effects³⁰;
2. There is relatively clear evidence for radiation-induced carcinogenesis for exposures exceeding 100 mSv^{27,31};
3. Radiation is a relatively weak carcinogen, and excess radiogenic cancer risk, if any, is considerably less than spontaneous cancer risk³²;
4. There are no parameters that allow a radiation-induced malignancy to be distinguished from a “naturally occurring” one³³;
5. The risk of radiation-induced malignancy is generally *inversely related to age*³⁰ and relatively higher in women compared with men^{32,34};
6. The risk for radiation-induced carcinogenesis from a CT scan is generally far less than the benefit of the information gained from appropriately indicated CT studies.^{29,35}

Additional detail concerning radiogenic cancer risk is available online.

Although conflicting interpretations are difficult to reconcile and data on both sides of the argument can be compelling, in practice, employing medical radiation only when necessary and substituting nonradiation utilizing procedures and dose-saving methodologies whenever possible should provide an optimal approach to balancing the immediate need for diagnostic information with patient safety.

MAGNETIC RESONANCE IMAGING

PHYSICAL PRINCIPLES

MRI is performed by magnetizing the patient's tissue slightly, generating a weak electromagnetic signal by applying a radiofrequency pulse, and mapping that signal spatially by manipulating its frequency and phase in a location-dependent manner with magnetic field gradients. MRI does not require mechanical motions of the scanner and therefore can image directly in nonaxial planes.

Although MRI uses electromagnetic radiation, the energy levels used in MRI are quite low (i.e., nonionizing). MRI appears to be remarkably free of significant bioeffects. Potential safety hazards in MRI relate to the extremely strong static magnetic field and rapidly switched gradient magnetic fields used and to the possibility of tissue heating from radiofrequency energy absorbed by the body. Tissue heating is a theoretic concern but, in practice, is not significant when conventional MRI techniques are used. Theoretically, the rapidly varying gradient magnetic fields could stimulate electrically excitable tissue, but this is not a problem with routine MRI techniques. In contrast, the powerful static magnetic field is a major safety hazard because the magnetic forces near a whole-body *magnetic resonance* (MR) imager are strong enough to cause significant projectile hazards. For example, an ordinary steel oxygen cylinder brought into an MRI examination room will fly into the bore of the magnet with a terminal velocity of about 45 mph. The possibility of displacements or torques on metallic

implants within patients also must be considered. Although the margin of safety is high, there are rare documented instances of harm to patients from dislodging intracranial aneurysm clips or intraocular metallic foreign bodies. Finally, the magnetic field can operate reed relays in cardiac pacemakers and cause a change in the pacing mode. Accordingly, strict security around MRI facilities is essential to prevent patients with certain types of metallic implants from entering the scanner and to prevent medical personnel from carrying into the scan room objects that could become projectiles.

MRI produces extremely high contrast between different types of soft tissue. This soft-tissue contrast is based on intrinsic properties of the tissues, but it can be modified and exploited by appropriate use of operator-selectable imaging techniques. The tissue properties normally utilized in MRI are as follows: the concentration of protons available to produce an MR signal (“proton density”), the presence of motion or blood flow, and two properties known as T1 and T2, time constants that describe how quickly an MR signal can be generated from a tissue (T1) and how quickly the MR signal, once generated, decays away (T2). In general, pathologic tissues have long T1 times and appear dark on those MR images whose appearance is conditioned primarily by T1 effects (“T1-weighted images”). Usually, pathologic tissues also have long T2 times and appear bright on T2-weighted images. The reason for this opposite behavior is that “T1” and “T2” describe processes that have opposite effects on the intensity of the MR signal. Flowing blood also can appear either bright or dark on MR images, depending on the examination technique used. The art of performing an MRI examination depends on appropriate manipulations of imaging techniques to capitalize on differences in proton density, flow, T1, and T2 between normal and pathologic tissue. In addition, the use of gadolinium-based MRI contrast materials, which alter the T1 and T2 of tissues semiselectively, has become important for numerous clinical applications, particularly *MR angiography* (MRA). MRI also can display other tissue properties such as molecular self-diffusion, temperature, and metabolites (MR spectroscopy), but these are less important for thoracic applications, although diffusion imaging and MR spectroscopy have recently shown some promise in lung cancer evaluation and staging.

TECHNIQUES

Motion during MRI causes artifacts that can degrade image quality severely. Motion compensation techniques, such as electrocardiographic gating and respiratory compensation, are widely used in chest MRI. High-speed techniques permit imaging in a matter of seconds, even fast enough to stop cardiac motion.

Direct MRI in sagittal, coronal, and oblique planes can provide superior depiction of structures that are oriented in the long axis of the body, such as the aorta, and of edges of structures that lie within the axial plane, such as lesions in the aortopulmonary window or lung apex.⁴⁸

Flow has profound effects on the MR image. Two basic effects from flow are seen in MRI; they are called “time-of-flight effects” and “spin-phase effects.” The manifestations of flow effects in MR images strongly depend on the type of

The primary source of controversy between those who believe low-level radiation exposures—exposures less than 100 mSv, which are typical for the exposures associated with medical imaging—may result in the development of malignancy and those who claim no such evidence exists lies with the *linear nothreshold* (LNT) model for radiation-induced carcinogenesis. The LNT theory holds that a straight-line relationship between radiation dose and cancer risk exists, and there is no threshold dose below which radiation is not carcinogenic.^{27,29} Proponents of the LNT theory hold that a linear model best describes the relationship between radiation exposure and cancer induction, and no evidence to support a departure from the LNT model exists^{36,37}; by contrast, critics of the LNT model for radiation-induced carcinogenesis risk prediction insist that the LNT model was developed to establish standards for protection of occupationally exposed individuals and overestimates the incremental risk for cancer development at low-level radiation exposures, and, therefore, it is inappropriate to project individual cancer risks from medical radiation exposures using this model.²⁷ Nevertheless, many of the widely publicized reports^{30,38-40} estimating the number of cancer-related deaths resulting from CT scanning have used the LNT methodology.

Estimates for the risk of radiation-induced carcinogenesis in humans primarily stem from epidemiologic studies of exposed patient cohorts, particularly Japanese survivors of the atomic bombings in 1945; other data sources include occupational radiation exposures and radiation accidents, such as the Three Mile Island and Chernobyl accidents.^{27,29,30,41} The LNT model is often used to extrapolate the elevated rate of malignancy found among these exposed cohorts to patients receiving the relatively low-level radiation exposures, typical of medical imaging, in the effort to estimate individual cancer risks; in addition, both the National Council on Radiation Protection and Measurements and the International Commission on Radiological Protection advise against the use of the effective dose paradigm and LNT theory in this fashion.³⁴ Furthermore, it should be understood that the LNT model does not provide for the ability to “sum” separate radiation exposures from temporally separated radiation-utilizing procedures into a “cumulative” cancer risk. In other words, regardless of the patient’s previous radiation exposures, the imaging study the patient is about to undergo only adds the potential incremental risk for cancer development attributable to that examination³⁴; the radiation exposures from separate examinations are not additive.^{34,42-44} This notion carries significant implications regarding the recent trend toward the development of radiation “dose registries,”⁴⁵ whereby patient medical imaging radiation exposures are tracked in a database with the intention of using such information to make future medical imaging decisions.

Low-Level Radiation-Induced Malignancy: Evidence for and Against

Investigators who assert that low-level radiation has carcinogenic potential cite the elevated incidence of malignancy noted in many large epidemiologic cohorts of exposed patients, particularly the Japanese atomic bomb survivors in the Life Span Study. This argument relies on the LNT

model to extrapolate the experience of these cohorts, exposed at relatively higher rates, to estimate the risks associated with the lower-level radiation exposures typical of medical imaging.³⁷ These investigators assert that a linear relationship (e.g., the LNT model) best describes the relationship between cancer rates and radiation exposures over a wide range of exposures; moreover, this relationship is consistently observed not only in the Life Span Study but in the analysis of other large epidemiologic studies of individuals exposed to radiation,³⁷ and that linearity best describes the responses of biologic systems to radiation exposure. Furthermore, experimental evidence can directly show cellular damage induced by radiation.³⁰ Finally, a recent large epidemiologic study focusing on younger patients undergoing CT scanning has shown a significant linear association between radiation dose to the brain and bone marrow and subsequent development of brain tumors and leukemia, respectively.^{35,46} This study evaluated 180,000 patients younger than 22 years undergoing nearly 280,000 CT scans in the United Kingdom between 1985 and 2002, who were subsequently followed for cancer development; the investigation specifically focused on brain tumors and leukemias, which are the cancers expected to appear first in irradiated pediatric patients^{35,46}; the risks for brain tumor and leukemia development in this patient cohort were small: it was estimated that one head CT may result in one excess brain tumor, for every 10,000 patients undergoing CT, in the first decade following the exposure.^{35,46} However, a recent editorial³⁵ also noted that the relatively short follow-up time in this study (average 10 years)⁴⁶ is insufficient to detect all potentially radiation-induced malignancies in this patient cohort, given that the latency of some radiation-induced malignancies may be as long as 20 to 40 years. Extrapolating the 10-year risk for radiation-induced carcinogenesis for the patients studied to lifetime carcinogenic risks for the exposed individuals yields estimates for cancer induction that are roughly similar to those asserted by the Life Span Study.³⁵ Note that this study⁴⁶ focused on pediatric patients, in whom the individual risks for radiation-induced malignancy are higher than for adults, but more than 90% of CT scans are performed in adult patients.³⁵

Investigators who challenge the notion that low-level radiation poses significant carcinogenic potential note the difficulties resulting from the reliance on the LNT model, as discussed previously, but also point to significant differences among the patients in the Life Span Study compared with those undergoing procedures utilizing medical radiation. Such differences include the following: that cancer incidence in Japan today is substantially different than in the United States, and that cancer incidence in both countries today is likely substantially different than in Japan in 1945.⁴¹ Medical imaging radiation exposure sources include relatively low energy x-rays and gamma rays, whereas atomic bomb explosions exposed patients to high-energy gamma rays, neutrons, and other charged particles⁴¹; medical imaging typically employs *fractionated* doses (radiation doses delivered intermittently over a period of time), whereas atomic bomb blasts exposures are instantaneous⁴¹; and Japanese atomic bomb survivors suffered uniform, whole-body exposures and radioactive fallout, whereas patients undergoing medical-imaging procedures

typically only expose limited body regions in a nonuniform fashion (the exception being some nuclear medicine procedures).⁴¹ Furthermore, the health of Japanese atomic bomb survivors was comparatively compromised, compared with patients undergoing medical imaging, owing to the limited resources for medical care, food, and shelter in Japan following the atomic bomb blasts.⁴¹ Thus, it seems clear that these substantial population differences limit the ability to extrapolate radiation-induced cancer incidence from one cohort to another.

In contrast to other investigators,³⁰ those who challenge the belief that low-level radiation has carcinogenic potential assert that the results of epidemiologic studies of radiation-induced carcinogenesis show no, or much smaller, health effects from radiation exposure than the data from the Life Span Study.⁴¹ Additionally, these investigators have called attention to serious limitations in the manner in which radiation-induced malignancy rates are calculated through the generation of “lifetime attributable risk” modeling.⁴¹

Lines of biologic evidence also call into question the simple notion that the rate of cancer induction is propor-

tional to the amount of radiation exposure. For example, it has been suggested that a 0.1 Sv radiation dose, which is at the upper limit of what is referred to as “low-level radiation,” is estimated to cause 0.004 long-term mutations per cell, which is a minor addition to the 1 mutation per cell per day that results from natural processes.⁴⁷ Furthermore, a number of in vivo experiments have shown a reduced rate of chromosomal aberrations following low-level radiation exposure due to stimulated production of DNA repair enzymes and immune system activation—the so-called “adaptive response.”^{31,47} Finally, the same survival curves plotted for Japanese atomic bomb survivors and other large-scale epidemiologic investigations of radiation effects, interpreted by some investigators as supporting the notion of a linear-dose response relationship between radiation exposure and carcinogenesis, are interpreted by others as showing a threshold effect, below which cancer is not induced, or in some cases, below which cancer risk actually decreases. The latter concept has been referred to as “hormesis” and is thought to be due to upregulation of protective mechanisms within cells and tissues induced by low-level radiation.^{31,47}

flow that is present and on the specific MRI techniques used. The clinical implication of this is that one can make the MR image of blood either bright (“white-blood images”) or dark (“black-blood images”). Most types of vascular pathology can be demonstrated with either white-blood or black-blood images, but there are usually clinical advantages to using one approach or the other in specific situations. Flow velocity can be estimated with MRI techniques, and thus noninvasive estimates of blood flow are potentially available.

Although high-speed imaging techniques are now available with MRI, it still is not an appropriate method to use for wide-ranging screening examinations of the entire trunk for metastatic disease. Such examinations normally should be performed with modern CT scanners. It usually is more rewarding to ask an anatomically focused question when requesting an MRI study.

APPLICATIONS OF CONVENTIONAL CHEST RADIOGRAPHY

SCREENING AND “ROUTINE” CHEST RADIOGRAPHS

It is now generally agreed that screening chest radiographs are not indicated except in specific high-risk populations.³⁷ Estimates as to possible iatrogenic disease caused by ionizing radiation from screening examinations, forecasts of possible genetic consequences, and financial concerns outweigh the medical value of such examinations. In 1973, the Department of Health, Education, and Welfare, in conjunction with the ACR and the American College of Chest Physicians, recommended the discontinuation of screening examinations. In 1985, recommendations of the ACR were more explicit: chest radiographs obtained for routine examination, preemployment screening,⁴⁹ prenatal or obstetric screening, and hospital admission, as well as repeated examinations of patients with positive tuberculin tests and a negative initial chest radiograph, should be eliminated. From their analysis of more than 10,000 chest radiographic examinations obtained in a hospital-based population, Sagel and associates²⁰ concluded that routine screening examinations done solely because of hospital admission or scheduled surgery are not warranted in patients younger than 20. Even in selected high-risk populations, radiographic screening for carcinoma of the lung has failed to significantly increase longevity.

The value of the routine hospital admission chest radiograph is still controversial. Although the yield is low in asymptomatic patients, the examination can be extremely valuable as a baseline study for comparison with radiographs taken during or after the course of hospitalization in patients who develop pulmonary symptoms.

DETECTION OF LUNG CANCER AND ASSESSMENT OF SOLITARY PULMONARY NODULES

Although chest radiographs are clearly useful in the initial evaluation of patients suspected of having lung cancer,

they are of limited accuracy in showing small or early cancers. At the time of their initial diagnosis, it is not uncommon for lung cancers to be visible retrospectively on prior radiographs.⁵⁰ Although additional radiographic studies, such as oblique views, are cost-effective for the initial evaluation of “nodular opacities” (see eFig. 18-13) that do not clearly represent a lung nodule and are often of value in determining that a “nodular opacity” is not a true nodule, studies by CT are superior for the detailed evaluation of a known lung nodule.⁵¹

EVALUATION OF INTENSIVE CARE UNIT PATIENTS

Chest radiography is generally the most common imaging study performed in the most critically ill patients in the hospital—those in the ICU. ICU radiographs are taken with portable and, therefore, suboptimal technique; nonetheless, the information they provide is useful and may alter patient management.⁹

The overall incidence of abnormalities found on chest films in ICU patients is quite high; in a study of more than 1000 consecutive medical or surgical ICU films obtained routinely or after a change in clinical status, malposition of a monitoring device or a marked change in apparent cardiopulmonary status was found in 65%.⁸ In a study of patients in a respiratory ICU,⁵² chest radiographs showed at least one new, clinically unsuspected finding in 35% of patients that, in 29% of these patients, led to a change in management. Significant findings are even more likely when the study is obtained to assess a change in clinical status. In intubated patients in a medical ICU, 43% of radiographs showed significant worsening of a known process or development of a new abnormality.⁵³ The value of obtaining chest radiographs on a daily basis in ICU patients is less clear. Strain and colleagues⁵⁴ found that routine morning radiographs revealed unsuspected abnormalities that led to a change in management in only about 15% of medical ICU patients, although this percentage was considerably higher (57%) in patients with pulmonary or unstable cardiac disease. Graat and coworkers⁵⁵ prospectively assessed the value of 2457 routine chest radiographs performed on patients in a combined medical and surgical ICU and found only 5.8% of routine chest radiographs showed new or unexpected findings; only 2.2% of patients required a change in management. Hall and colleagues⁵⁶ found that 18% of mechanically ventilated patients in a medical/surgical ICU had at least one radiograph that showed a clinically significant and unsuspected finding. The value of daily chest radiography in patients who have undergone thoracotomy and pulmonary resection has also been challenged. Daily chest radiography in nonhypoxic patients who had recently undergone thoracotomy and pulmonary resection changed care in only 27% of patients, whereas chest radiography altered management in 79% of such patients who were hypoxic.⁵⁷ Finally, a meta-analysis of 8 studies totaling 7078 patients found that elimination of daily routine chest radiography did not affect hospital or ICU mortality and there was no difference in length of stay in either the ICU or hospital, or the period required for mechanical ventilation, between patients undergoing routine daily chest radiography and those receiving

“on-demand” imaging.⁵⁸ Similarly, Hejblum and associates⁵⁹ concluded that an on-demand strategy for ordering chest radiographs for mechanically ventilated patients in the ICU is associated with a 32% reduction in the use of chest radiography compared with a routine daily strategy, but both strategies result in a similar rate of therapeutic or diagnostic intervention. On the basis of these results, the ACR has recommended that portable chest radiography should be obtained only for clinical indications, not routine assessment, when monitoring a stable patient or for a patient undergoing mechanical ventilation in the ICU.⁶⁰ Furthermore, routine chest radiography is not recommended for stable patients admitted to the ICU for cardiac monitoring or for stable patients admitted to the ICU for extrathoracic disease only.⁶⁰ Chest radiography is still recommended for the assessment of patients following initial support device placement, including endotracheal intubation, central venous catheter insertion, pulmonary arterial catheter placement, nasogastric tube placement, and thoracostomy tube insertion.⁶⁰

INDICATIONS IN ACUTE LUNG DISEASE

Dyspnea

Two studies suggest that chest radiography should be used routinely in patients with acute or chronic dyspnea.^{61,62} In one study, new, clinically important radiographic abnormalities requiring acute intervention or follow-up evaluation were identified in 35% of 221 symptomatic patients.⁶¹ Another study found that acute dyspnea was a strong predictor of a radiographic abnormality, but mainly in patients older than 40.⁶³ In this group, 86% of dyspneic patients had abnormal chest radiographs, whereas radiographs were abnormal in only 31% of patients younger than 40. Only 2% of patients younger than 40 with a normal physical examination had abnormal radiographs indicative of an acute abnormality. The ACR⁶⁴ recommends chest radiography when dyspnea is chronic or severe or when additional risk factors are present, such as age older than 40; known cardiovascular, pulmonary, or neoplastic disease; or abnormal physical findings.

Acute Respiratory Symptoms

Opinions are also divided about the utility of chest radiographs in patients with suspected acute lung disease and symptoms other than dyspnea. In a study of 1102 outpatients with acute respiratory disease, Benacerraf and coworkers⁶³ found patient age, results of physical examination, and presence or absence of hemoptysis to be important factors in predicting the value of radiographs; only 4% of patients younger than 40, without hemoptysis and without detectable abnormalities on physical examination, had acute radiographic abnormalities, whereas a much higher incidence of radiographic abnormalities was present if the patient was older than 40, had hemoptysis, or had abnormal physical findings. Heckerling,⁶⁵ in a study of 464 patients with acute respiratory symptoms, found a low incidence of pneumonia (3%) in patients with a negative physical examination, except in those with dementia. Whenever pneumonia is suspected in adults, the American Thoracic Society recommends PA (and lateral when possible) chest

radiography although the impact of chest radiography on clinical outcomes in patients with lower respiratory tract infections remains unclear.^{65a} In this setting, chest radiography may be useful to determine which patients should be hospitalized and which patients should be classified as having “severe” pneumonia.⁶⁶ The ACR considers chest radiography appropriate in immunocompetent patients with acute respiratory illnesses when one or more of the following is present: patient older than 40; dementia, positive physical examination findings; hemoptysis, hypoxemia, leukocytosis, and a number of other risk factors, including coronary artery disease, congestive heart failure, or drug-induced respiratory failure.⁶⁷ For patients younger than 40 with an acute respiratory illness but without such additional findings, chest radiography is generally not routinely indicated. Chest radiography is also considered appropriate for any patient clinically suspected of pneumonia.⁶⁷

Acute Asthma

Chest radiography is uncommonly used to make a diagnosis of asthma; radiographs are often normal, and visible abnormalities in this disease are usually nonspecific.⁶⁸ Although Petheram and associates⁶⁹ reported that 9% of 117 patients with severe acute asthma had unsuspected radiographic abnormalities affecting management, the usefulness of radiography in both adult and pediatric^{69a} patients with an established diagnosis of asthma who suffer an acute attack is limited. Correlation between the severity of radiographic findings and the severity or reversibility of an asthma attack is generally poor,⁶⁸⁻⁷⁰ and radiographs provide significant information that alters treatment in 5% or fewer patients with acute asthma.^{65,71,72} Although it is difficult to generalize regarding the role of radiographs in both adults and children with acute asthma, chest imaging should be used to exclude the presence of associated pneumonia or other complications when significant symptoms and/or appropriate clinical or laboratory findings are suggestive.^{68,70,72} The ACR considers chest radiography warranted in adult patients with asthma when a clinical suspicion for pneumonia or pneumothorax is present, or unless one or more of the following is noted: chest pain, edema, leukocytosis, or the patient has a history of either coronary artery disease or congestive heart failure.⁶⁷

Exacerbation of Chronic Obstructive Pulmonary Disease

Chest radiographs are often used in the initial assessment of patients with suspected COPD; however, they are of limited value in patients with known COPD who present with worsening of their disease.^{72,73} In a study of 107 patients with COPD presenting with an exacerbation of symptoms, only 17 (16%) had an abnormal chest radiograph, and in only half of these did the radiographic findings result in a significant alteration in management.⁷² In another study, including patients with both COPD and asthma, the management of 21% of patients was altered by radiographic findings.⁷³ It has been recommended that chest radiographs be obtained in patients with COPD only if certain clinical indicators are present; in various studies, these have included a clinical suspicion for pneumonia or pneumothorax, a history of coronary artery disease or congestive heart failure, leukocytosis, chest pain, peripheral

Figure 18-11 Chest CT shows typical findings of rounded atelectasis. **A**, Frontal chest radiograph shows volume loss in the left lower lobe associated with an oblong mass (arrow) and left-sided pleural abnormality. **B**, Axial chest CT in lung windows shows a subpleural left lower lobe mass (arrow) associated with left lower lobe volume loss (posterior displacement of left major fissure, small volume in the left lower lobe). Note “spiraling” appearance of left lower lobe bronchovascular bundles as they extend into the mass (arrowheads); this is the so-called comet-tail sign. **C**, Axial chest CT displayed in soft-tissue windows shows other features consistent with rounded atelectasis including abnormally thickened pleura (arrowheads) and contact of the mass (arrow) with the abnormal pleura. (Courtesy Michael Gotway, MD.)

edema,⁶⁷ intravenous drug abuse, fever, seizure, immunosuppression, and other pulmonary disease. When such indicators are used as a guide, nearly all patients with significant findings will have radiographs performed; moreover, it should be noted that more than two thirds of patients in one study met inclusion criteria for performing radiography.⁷³

In most patients with an established diagnosis of cystic fibrosis, clinical findings and chest radiographs are often sufficient for clinical management. Conversely, it should be recognized that patients with cystic fibrosis can have a significant exacerbation of their symptoms with little visible radiographic change.

APPLICATIONS OF CROSS-SECTIONAL IMAGING TECHNIQUES

SOLITARY PULMONARY NODULES

Assessment of a *solitary pulmonary nodule* (SPN) seen on chest radiographs is a common indication for CT.^{51,74} CT is used to confirm that the SPN is real, to confirm that the SPN is solitary, to attempt further noninvasive characterization of the lesion, to guide percutaneous biopsy of the lesion, and to provide staging information if the SPN is found to represent a carcinoma. The likelihood of malignancy in such nodules varies from less than 10% in mass screenings to about 50% among resected nodules.

In general, CT of a patient with an SPN should be performed with thin-section volumetric imaging to provide detailed analysis of nodule morphology and to allow identification of the presence of fat or calcium (see Fig. 18-10, Video 18-6) within the nodule, and when the latter is present, the pattern of calcification; this is now fairly routine in the era of MSCT technology.

Figure 18-12 Chest CT of bronchogenic carcinoma. Axial CT displayed in lung windows shows a spiculated lesion within the left upper lobe. (Courtesy Michael Gotway, MD.)

In up to 20% of instances, a “lung nodule” visible on chest radiographs actually represents an artifact, chest wall lesion (eFig. 18-24), or pleural abnormality; in some cases, CT is essential to determine the true nature of the opacity. CT can be useful to define the morphology of the SPN and suggest whether it is benign, likely malignant, or indeterminate, in other words, having neither benign nor malignant characteristics. In some patients, a specific diagnosis of lesions such as rounded atelectasis (Fig. 18-11, Video 18-7), a mucous plug, or arteriovenous malformation (Video 18-8) can be made on the basis of CT findings, indicating the benign nature of the lesion.^{51,74} Other CT appearances suggest the presence of malignancy (eFig. 18-25).⁵¹ Malignant features include a spiculated (see eFig. 18-25D) or irregular contour; the presence of air bronchograms within the nodule (see eFig. 18-25A), bubbly air collections (“pseudocavitation”), or cavities; and a diameter larger than 2 cm (Fig. 18-12, see eFig. 18-25A).^{51,74} Benign features include the presence of several patterns of calcification; “benign” patterns include diffuse, central, laminated,

and chondroid, or “popcorn,” calcification (Fig. 18-13).^{51,74} In about 30% of benign nodules, calcium not readily visible on chest radiographs can be seen on thin-section CT (eFigs. 18-26 and eFigs. 18-27). Carcinomas may occasionally show calcification (eFig. 18-28), although often in an eccentric or stippled pattern. The presence of fat within an SPN, indicated by a low CT attenuation coefficient (Fig. 18-14), strongly suggests the presence of hamartoma^{51,74} or lipoid pneumonia (eFig. 18-29); such nodules can be safely followed with serial radiographs.

Figure 18-13 Chest CT of hamartoma. Chest CT showing “popcorn” (chondroid) calcification within a left upper lobe nodule (arrow), consistent with hamartoma. (Courtesy Michael Gotway, MD.)

Figure 18-14 Chest CT of a hamartoma. CT image showed low attenuation within the solitary pulmonary nodule (typical CT numbers within the lesion ranged from -90 to -100 HU), consistent with fat. (Courtesy Michael Gotway, MD.)

Malignant tumors tend to show greater enhancement than benign nodules after the rapid injection of iodinated contrast material.⁷⁵⁻⁷⁸ Because the degree of enhancement depends on the amount and rapidity of contrast infusion, it is important to use a consistent technique. Using a specific contrast enhancement CT protocol, a threshold for enhancement of 15 HU or more is typically seen with malignancy, hamartoma, and some inflammatory lesions. Enhancement of less than 15 HU almost always indicates a benign lesion, usually a granuloma. Therefore, whereas positive results (enhancement of >15 HU at any time point during the study) are nonspecific, negative results are quite useful (eFig. 18-30). This technique has been shown to have a sensitivity of 98% and a specificity of 58% in diagnosing carcinoma. More importantly, the negative predictive value of this technique is approximately 96%.⁷⁷ CT nodule enhancement studies are most appropriately used for patients who have indeterminate nodules (i.e., those without typical benign or malignant appearances). A similar use for dynamic, contrast-enhanced MRI has been reported, although data are limited.⁷⁹ The use of *fluorodeoxyglucose positron emission tomography* (PET) imaging (see Chapter 21) has also been shown to be useful for distinguishing benign from malignant nodules (see Fig. 21-1)⁸⁰ and is generally favored over contrast-enhanced CT for additional imaging characterization of indeterminate lung nodules. In a meta-analysis,⁷⁹ PET was shown to be 94% sensitive and 83% specific for the differentiation of benign from malignant solid nodules 1 to 3 cm in size. The addition of PET-CT tends to increase sensitivity with no change in specificity compared with PET alone.⁸¹ False-positive PET results may be seen with inflammatory processes, particularly granulomatous diseases⁷⁹ such as tuberculosis (see eFig. 53-6C and D), histoplasmosis, and sarcoidosis. Tumors that may be ^{18}F PET-negative include minimally invasive adenocarcinoma (see Fig. 21-2, eFig. 53-7A), carcinoid tumors,⁷⁹ and some metastases (e.g., renal cell carcinoma).⁸² In addition, small nodules may not be of a sufficient size to produce a positive result with PET scanning (see eFig. 53-7F). The sensitivity of PET imaging significantly decreases with nodules measuring less than 8 to 10 mm in diameter (see eFig. 53-7F). As with any imaging modality, the correlation of the PET results with morphologic features on CT, prior radiographic examinations, and the clinical presentation will improve the determination of the likelihood of malignancy.

MULTIPLE PULMONARY NODULES

CT is the favored procedure for identifying multiple pulmonary nodules or masses. It detects more and smaller metastases (Fig. 18-15, Video 18-9) than any other imaging technique, and 2- to 3-mm nodules are routinely visible.⁸³⁻⁸⁵ This is most relevant for patients with extrathoracic malignancies, in whom the detection of metastatic disease has a major impact on initial staging and assessment of response to therapy. The major sources of controversy regarding the use of CT for evaluation of possible metastases have been its limited specificity and cost-benefit ratio.⁸⁴

CT is clearly more sensitive than chest radiographs in diagnosing multiple pulmonary nodules in patients with suspected metastasis.⁸³⁻⁸⁵ The sensitivity of CT for detecting

Figure 18-15 Chest CT in a patient with metastatic cervical carcinoma. Maximum-intensity projected CT shows numerous bilateral pulmonary nodules (arrows) that were not visible on the chest radiograph. CT is more sensitive than radiography for detection of small nodules of any cause. (Courtesy Michael Gotway, MD.)

surgically proven nodules ranges from 50% to 75% (i.e., 50% to 75% of all resected nodules are seen on preoperative CT scans), whereas the sensitivity of chest radiographs is about 25%. In some studies, most nodules (55% to 60%) seen on CT and subsequently resected have proved to be benign (granulomas, intrapulmonary lymph nodes, and the like).⁸⁶ In other studies, most CT-detected nodules (80% to 95%) have proved to be metastatic lesions.⁸⁷ In an older study from the pre-MSCT era involving radiologic-surgical correlation, Peuchot and Libshitz⁸⁷ evaluated 84 patients with previously documented extrathoracic malignancies and newly identified pulmonary nodules. These authors noted important limitations in both the sensitivity and specificity of CT. Of a total of 237 nodules resected, CT was able to identify only 173 (73%); 207 (87%) were metastatic tumors, 21 (9%) were benign, and 9 (4%) were bronchogenic carcinomas. Of 65 nodules interpreted as solitary on chest radiographs, CT disclosed multiple nodules in 46%, and 84% of these additional nodules were metastases. Although exquisitely sensitive for small nodule detection, CT is not infallible. In a study of 53 preoperative patients undergoing 60 metastectomy surgeries from 1996-2004, in whom nodules detected at chest CT were compared with pathologically confirmed metastases, 46% to 47% of surgically palpable lung metastases were not reported at preoperative CT.⁸⁸ Although there are intrinsic biases affecting such reports, including the possibility that surgical palpation will detect benign nodules and may overlook some malignant nodules that will subsequently manifest as growing nodules at chest CT, as well as the inherent difficulties correlating the location of nodules detected at chest CT with pathologic specimens, the results of this study nevertheless highlight the limitations of chest CT for small nodule detection and characterization.⁸⁸

Accordingly, CT results must be interpreted in light of the clinical characteristics of the patient. Primary tumors that commonly spread to the lungs, more advanced malignancies, and the absence of any simulators of metastases (sarcoidosis, sarcoidosis, and prior granulomatous infection) would favor malignancy in pulmonary nodules detected by CT. Furthermore, smaller and less numerous nodules are more likely to be benign. The findings on CT are in themselves not specific, however, and follow-up may be necessary to demonstrate the growth or stability of small nodules.

LUNG CANCER STAGING

In patients with lung cancer, accurate anatomic staging is essential for planning the therapeutic approach.^{89,90} CT is used in both assessment of primary tumor extent and detection of lymph node metastases. However, its accuracy in both situations is limited.^{89,90} Lung cancer staging is reviewed in detail in Chapter 53.

Computed Tomography

The primary goal of CT is to help distinguish patients who likely have resectable tumors from those who do not.⁹¹ Pulmonary malignancy is considered to be likely unresectable (stage T4) if the primary tumor (1) involves the trachea (eFig. 18-31) or carina; (2) invades the mediastinum (eFig. 18-32) with involvement of mediastinal structures (eFig. 18-33); (3) invades the chest wall with involvement of great vessels, brachial plexus (see eFig. 53-18), or vertebral column (eFig. 18-34); or (4) results in a malignant pleural effusion or pleural implants (eFig. 18-35, see eFigs. 53-4 and eFig. 53-5).⁹²⁻⁹⁵ Note, however, that acceptable morbidity and mortality have been reported following en bloc vertebral body resection with reconstruction for neoplasms invading the spine, particularly following induction chemotherapy,⁹³ but such extensive surgeries are relatively restricted to larger academic or high-volume centers. The presence of satellite nodules in the same lobe as the primary tumor (see eFig. 53-19) is now designated as T3 in the seventh edition of the TNM Classification of Malignant Tumors and does not preclude surgical resection.^{93,94}

Tracheal (see eFig. 18-31) or carinal invasion (eFig. 18-36) can be suggested with CT but requires biopsy confirmation. The CT diagnosis of chest wall (see eFig. 53-16) or mediastinal (see eFig. 18-32) invasion can be a problem, and many CT scans suggesting chest wall invasion are relatively nonspecific and can be seen with a number of inflammatory disorders. The sensitivity and specificity of CT for diagnosing T4 mediastinal or chest wall invasion are about 60% and 90%,^{96,97} respectively, although some findings (e.g., vertebral body destruction, encasement of mediastinal structures, mediastinal fat infiltration) are virtually diagnostic.⁹³⁻¹⁰¹ Limited chest wall or mediastinal invasion is considered potentially resectable by many surgeons, but knowledge of tumor extent is nonetheless an important factor when planning therapy.

CT findings suggesting mediastinal invasion^{97,99} include (1) replacement of mediastinal fat by soft-tissue attenuation; (2) compression or displacement of mediastinal vessels by tumor; (3) tumor contacting more than 90 degrees of the circumference of a structure such as the aorta or pulmonary artery (the greater the extent of circumferential contact, i.e., 180 degrees, the greater the likelihood of invasion); (4) more than 3 cm of contact between tumor and the mediastinum; and (5) obliteration of the mediastinal fat plane normally seen adjacent to most mediastinal structures (see eFig. 18-32 and eFig. 18-37). However, individually, these findings are unreliable for differentiating mediastinal invasion from anatomic contiguity.⁹⁹

CT is of little value in the diagnosis of malignant pleural effusion because this diagnosis requires cytologic confirmation.¹⁰² However, in some patients, CT may show diffuse or nodular pleural thickening with (see eFig. 53-4) or without

(see eFig. 18-35 and eFig. 53-5) pleural liquid.^{102,103} PET may show tracer uptake in patients with malignant pleural effusion (see eFig. 53-4), even when CT does not show evidence of nodular pleural thickening and when cytologic analysis is negative.¹⁰⁴

The diagnosis of mediastinal lymph node metastasis by CT is determined largely by node size, although the preservation of fat within lymph nodes often reflects the absence of pathologic infiltration, whereas necrosis may imply pathologic infiltration even within normal-sized lymph nodes.⁹⁰ By convention, a nodal short axis diameter of 1 cm or greater is considered to be abnormal in all node stations (Fig. 18-16),^{90,94} except the subcarinal space.^{105,106} In general a tumor cannot be detected in normal-sized lymph nodes by CT, and there are no characteristic appearances allowing benign and malignant causes of nodal enlargement to be distinguished (see eFigs. 53-1 and 53-3).¹⁰⁶⁻¹⁰⁸ Pooled information from 35 studies published between 1991 and June 2006 evaluating the performance of CT scanning for noninvasive staging of the mediastinum has shown that this size threshold has a sensitivity of only about 51% and a specificity of 86% for diagnosing mediastinal lymph node metastases in patients with lung cancer.^{95,109,110} Furthermore, the accuracy of CT for detecting involvement of individual node groups is low, perhaps as low as 40%.¹⁰⁹ In a more recent review⁹⁰ of the accuracy of mediastinal lymph node staging using CT, a combination of studies evaluating 7368 patients found the median sensitivity and specificity for mediastinal lymph node metastases detection at chest CT of 55% and 81%, respectively.

Despite its limited accuracy, CT, particularly in conjunction with PET, is useful in determining the need for preoperative mediastinoscopy. Furthermore, CT may also be useful in deciding on the need for preoperative mediastinoscopy, anterior mediastinotomy (e.g., the Chamberlain procedure), or suggesting alternate procedures for lymph node

staging (e.g., needle biopsy, endoscopic and/or endobronchial ultrasound).

Perhaps the most important potential contribution of CT to intrathoracic staging is precise mapping of nodes likely to be involved by tumor, and to thereby direct additional diagnostic procedures required for accurate lung cancer staging.

Positron-Emission Tomography and Positron-Emission Tomography–Computed Tomography

The role of PET imaging in the staging of bronchogenic malignancy is explored in detail in Chapters 21 and 53. The primary value of PET is to increase the sensitivity for the detection of local and distant malignancy in order to prevent patients with unresectable disease from undergoing unnecessary surgery. PET and PET-CT are most useful for evaluating the N (Fig. 18-17) and M components of staging, although PET activity in the primary tumor (T component) may provide insight into biologic aggressiveness and the chance of future spread of early localized tumors.¹¹¹

Magnetic Resonance Imaging

There are few situations in which MRI is the preferred imaging modality for patients with primary lung cancer. The extent of chest wall invasion adjacent to a lung tumor sometimes may best be shown by MRI, and there may be some advantage to MRI over CT for assessment of mediastinal invasion, vertebral body invasion, and involvement of the chest wall.⁹⁰ Sagittal or coronal MR images can be advantageous in delineating the extent of tumors at the lung apex (see eFig. 53-18B and C).^{90,112} Consequently, MRI is more accurate than CT for determining chest wall involvement in superior sulcus tumors; moreover, involvement of the neurovascular bundle¹¹² is better shown with coronal and sagittal MRI than with axial CT images (see eFig. 53-18B and C).

Figure 18-16 Chest CT performed for staging in a patient with non-small cell lung cancer. **A**, The primary tumor was present at another level in the right lung. Right paratracheal lymphadenopathy (arrow) is present; left mediastinal nodes also appear enlarged. **B**, Axial chest CT at a slightly lower level shows left hilar and subaortic (arrowhead) lymph nodes, which measure greater than 1 cm in short axis diameter, the most widely accepted size threshold for abnormality, and would be considered suspicious for metastasis. (Courtesy Michael Gotway, MD.)

Figure 18-17 PET-CT in the staging of pulmonary malignancy. This patient was diagnosed with non-small cell lung cancer, and CT and PET-CT were performed for staging. **A**, The primary tumor is visible in the peripheral right lung (*). Borderline right paratracheal lymph nodes (arrow) are present. **B**, PET-CT shows intense tracer uptake in the primary right lung neoplasm, as well as within the right paratracheal lymph nodes (arrow). The latter finding prompted mediastinoscopy, which confirmed metastatic nodal disease. (Courtesy Michael Gotway, MD.)

In most patients with primary lung cancer, MRI has no unique information to offer and CT is the preferred imaging procedure.⁹⁰ MRI is similar to CT in its ability to identify mediastinal lymph nodes⁹⁰ and to diagnose mediastinal metastases. Although it has been reported that MRI is more accurate than CT in detecting mediastinal,^{90,95,113} cardiac, or vascular invasion by lung cancer, the reported differences in accuracy are small. In general, the MR properties of benign and tumor-bearing mediastinal lymph nodes do not differ significantly in most patients and, as with CT, node size is usually the main diagnostically useful discriminator. However, recent data with newer MR sequences—particularly diffusion-weighted imaging,¹¹⁴ *short-tau inversion recovery imaging* (STIR),^{115,116} and recent observations regarding findings at T2-weighted chest MRI¹¹⁷—may allow discrimination between benign and malignant lymph node involvement, even for lymph nodes with short axis dimensions less than 1 cm. In addition, in some cases, MRI is able to demonstrate masses better than CT by imaging in the coronal or sagittal plane and, in some cases, MRI may be used as a problem-solving tool.

Brachial Plexopathy

Imaging of the brachial plexus is useful for patients with suspected metastatic disease, radiation injury, primary tumor, or traumatic injury. Clinical evaluation can suggest possible etiologies of brachial plexopathy and whether the neurologic deficit is more likely due to a central or a peripheral lesion.¹¹⁸ However, clinical evaluation cannot demonstrate the pathology and localize precisely the site of involvement.

Metastatic disease and radiation injury are the most common causes of brachial plexopathy, and the clinical distinction between these is difficult, although pain, Horner syndrome, and lower trunk involvement are characteristic of metastatic involvement.^{119,120} CT is of proven value for patients with primary or metastatic tumors,^{118,121} but it may be less useful for patients with radiation fibrosis. CT is superior for the detection of osseous involvement due to

superior sulcus tumors.¹¹² Older data clearly indicated that MR is superior to CT for assessment of brachial plexus involvement by lesions within the superior sulcus, primarily due to the multiplanar capabilities of MR. However, as mentioned previously, advances in CT technology now allow imaging reconstruction in any plane, and it is likely that these improvements have enhanced the diagnostic capabilities of CT for assessment of superior sulcus tumors. Nevertheless, MR possesses inherently superior contrast resolution to CT, which is a valuable property for imaging the superior sulcus region. Therefore, MR is still considered the reference standard for evaluation of tumors within the superior sulcus and for assessment of brachial plexus involvement by tumors in this region.^{90,112}

CT myelography, often in conjunction with conventional myelography and MR imaging, is the optimal imaging modality for the assessment of traumatic brachial plexus injury.¹²²

LUNG CANCER SCREENING

The utility of CT for lung cancer screening was a subject of significant controversy, but with the publication of the results of the *National Lung Screening Trial* (NLST),¹²³ the benefit of CT lung cancer screening for high-risk smokers is no longer in doubt. Before the NLST, a number of cohort studies had suggested significant benefit to lung CT screening in smokers, but these studies were persistently questioned due to various biases, including lead-time bias, length-time bias, and overdiagnosis bias, inherent to non-randomized studies. Many of these screening studies showed a high percentage of early-stage cancers found, suggesting early detection and a greater chance of cure. For instance, in the International ELCAP study,¹²⁴ 85% of cancers detected were stage I. Because none of these studies had a control arm, the mortality benefit from early diagnosis assumes that lung cancer is an invariably fatal disease; however, this is not necessarily true. Despite these encouraging results, the prospect of biases in study design

prevented acceptance of the use of CT for lung cancer screening and highlighted the need for randomized, controlled trials to settle the debate.

A second potential issue with lung cancer screening is the high incidence of nonmalignant pulmonary nodules detected. According to the Mayo Clinic data,¹²⁵ 74% of patients had at least one nodule detected during the 4-year study period and only 2% of noncalcified nodules were found to be malignant. Given that most patients with nodules are followed with CT to demonstrate 2 years of stability, the acceptance of lung cancer screening would undoubtedly result in a large number of subsequent CT scans that would not have otherwise been performed. This could have a significant impact on the cost-effectiveness of lung cancer screening and radiation exposure in this patient population. Ongoing research efforts have been directed at identifying the populations most appropriate to undergo lung cancer screening with CT and how to optimize the approach to abnormalities detected at screening, in particular to limit false-positive results, and to develop strategies for management of nodules detected at CT screening.

Although a number of nonrandomized studies evaluating the ability of screening with CT to reduce all-cause and lung cancer-specific mortality have been published, and several randomized trials are ongoing (particularly in Europe), the NLST data¹²³ represent the largest randomized, controlled trial of lung cancer screening with CT to date. Between August 2002 and April 2004, 53,454 asymptomatic patients, at high risk for pulmonary malignancy, at 33 academic medical centers in the United States, were enrolled and randomized to undergo three annual screenings with low-dose chest CT (26,722 participants) or single-view posteroanterior chest radiography (26,732 patients). “Low-dose” chest CT reduces the effective dose to approximately 2 mSv compared with the 5–8 mSv typical of “standard-dose” chest CT (see Table 18-2). “High-risk” eligible patients were defined as patients 55 to 74 years old, with at least a 30-pack-year smoking history and who were either current smokers or smokers within the previous 15 years. Eight participants had lung cancer and another seven died before the first screening, leaving 26,715 patients in the low-dose CT screening group and 26,724 in the chest radiography screening group.¹²³ Additional baseline patient characteristics of the NLST study group included 59% men with an average age of 61 (± 5) years, and 91% of the patients were Caucasian. The mean smoking duration was 43 pack-years and 48% of patients were current smokers.¹²³

The first scheduled screening was successfully performed in 98.5% ($n = 26,309$) of patients in the low-dose CT group and 97.4% ($n = 26,035$) of patients in the chest radiography group. No difference in compliance with screening was noted between the two groups.¹²³

A “positive” screening result at low-dose CT was defined as the detection of any noncalcified nodule at least 4 mm in any diameter, whereas a positive result at chest radiography was defined as any noncalcified nodule or mass “suspicious for” lung cancer. The presence of lymphadenopathy or pleural effusion could be considered a positive result as well. The proportion of positive screening results was higher in the low-dose CT screening group (24.2%) compared with the chest radiography screening group (6.7%) over all three rounds of screening, and overall, 39.1% of patients

undergoing low-dose screening with CT had at least one positive screening result, whereas 16% of those in the chest radiographic arm had at least one positive result. The proportion of patients with negative screening results, but with significant incidental findings, was over three times higher in the low-dose CT group compared with the group screened with chest radiography (7.5 vs. 2.1%, respectively).¹²³

Across the three rounds of screening, 96.4% of the positive results at low-dose CT and 94.5% of the positive results at chest radiography were false-positive results.

A total of 1060 lung carcinomas (645 per 100,000 person-years) were diagnosed in the low-dose CT screening group, and 941 (543 per 100,000 person-years) lung cancers were diagnosed through chest radiography. The proportion of stage I lung carcinomas among those with positive screening results in the low-dose CT screened group was 63%, whereas this value was 47.6% in the chest radiograph-screened group.¹²³ A preponderance of adenocarcinomas was found in the CT-screened group. A 20% relative reduction in lung cancer-specific mortality was found in the low-dose CT screened group at 6 years following the initial prevalence scan and two rounds of screening, compared with the chest radiography screened group. Similarly, all-cause mortality was decreased by 6.7% in the low-dose CT screened group compared with the group screened by chest radiography.¹²³ It has been noted that the mortality benefit of lung screening with CT is likely greater than the 20% reduction reported in the NLST because this trial was halted early when analysis showed that the target level for lung cancer mortality reduction had been reached.¹²⁶ Although both CT screening and chest radiography were associated with relatively high false-positive rates, most of the false-positive findings underwent serial evaluation, rather than invasive testing, and therefore complications related to invasive diagnostic evaluation were uncommon.

Following the publication of the successful results observed in the NLST, a number of organizations, including the National Comprehensive Cancer Network,^{127,128} the American Lung Association,^{127,129} the American College of Chest Physicians, the American Society of Clinical Oncology,^{127,130} the American Cancer Society,¹³¹ the American Thoracic Society,^{130,132} the American Association for Thoracic Surgeons,^{127,133} and, most recently, the U.S. Preventive Services Task Force^{134–136} have now endorsed low-dose CT screening for lung cancer in high-risk patients. Nevertheless, a number of questions remain unanswered¹³⁷:

1. Will patient populations with risk profiles different from those studied in the NLST benefit from low-dose CT screening?
2. Are less frequent CT screening intervals as effective as yearly screening, and how long should screening continue? A recent evidence-based guideline suggests annual low-dose CT screening in high-risk individuals for 3 consecutive years and, if these studies are negative (defined as no solid nodule ≥ 5 mm or *ground-glass opacity* [GGO] nodule ≥ 8 mm), biannual screening thereafter¹³⁷;
3. How should lung nodules detected at low-dose CT screening, the vast majority of which represent false positive findings, be managed?

4. Would different criteria for a “positive” screening result enhance or detract from the efficacy of CT screening?
5. Can the results of the NLST be extrapolated to community practice? Importantly, the NLST was conducted among centers with recognized excellence in diagnostic imaging and thoracic surgery, and one of the most important factors influencing the success of lung cancer screening—the mortality associated with thoracic surgery—was only 1% in the NLST, which was substantially lower than the 4% mortality rate reported for the population in the United States in general.^{123,138}

Initial studies^{139,140} of the cost-effectiveness of lung cancer screening with CT suggest that low-dose CT performed in high-risk, commercially insured patients, typically using patient selection criteria similar to that used in the NLST, compares favorably with other widely accepted screening programs, such as screening for cervical, colorectal, and breast malignancies.¹⁴⁰ One such analysis suggested that the cost-per-life saved for lung carcinoma screening with low-dose CT is less than \$19,000 and is still less than \$27,000 in the “highest-cost” scenario, with both values less than the costs for screening programs already recommended by the U.S. Preventive Services Task Force.¹³⁹ When approached from the payer perspective, the additional cost per commercial insurance plan member per month for low-dose lung cancer CT screening was \$0.76 in 2012, compared with \$2.50, \$1.10, and \$0.95 for breast, cervical, and colorectal cancer screening, respectively.¹⁴⁰ Adding smoking cessation programs to low-dose CT screening efforts further improves the cost-effectiveness of lung cancer screening with CT.¹⁴⁰

Finally, although the NLST has provided great optimism for the reduction of lung cancer–related mortality, this optimism has been somewhat tempered by the lack of a similar lung cancer mortality reduction from CT screening in several European trials.^{132,141–143} Such results raise the possibility that the magnitude of the benefit of CT screening for lung cancer may not be fully realized in community practice. It has been noted that the lack of mortality reduction from CT screening in these other trials^{132,141–143} may be the result of the smaller sample size of these trials^{132,141–143} compared with the NLST (number of patients randomized to the intervention arm ranging from 1202 to 2052 in the smaller studies^{132,141–143} vs. 26,722 in the NLST), but several peculiar features of the NLST raise questions regarding the generalizability of this trial. Such features include far greater adherence with screening follow-up among NLST patients (>90%) than may be expected in practice and that NLST patients were more highly educated and less likely to be current smokers compared with the general population, suggesting that NLST patients may be healthier than patients in the general population eligible for CT screening.¹³² Additionally, questions regarding the potential harms of CT screening for lung cancer remain when this procedure is applied to individuals in the general population. Taken together, these concerns indicate that programs for lung cancer screening using CT must be implemented in the safest and most effective manner, and future research efforts to identify such methods remains of critical importance.^{132,144}

Figure 18-18 Chest CT for localization of mediastinal masses. An axial CT image shows an anterior mediastinal soft-tissue mass (M). There are no characteristic attenuation features (e.g., fat, calcium). The location of the mass, however, is precisely documented, and thus the differential diagnosis was limited and biopsy facilitated. The lesion was a seminoma. (Courtesy Michael Gotway, MD.)

HILAR AND MEDIASTINAL MASSES

CT is indicated as the primary imaging modality in most patients with suspected hilar or mediastinal masses. The cross-sectional display and tissue discrimination of CT have revolutionized diagnostic imaging of the hilum and mediastinum.

Lesions can be detected with high sensitivity and located precisely to their structure of origin or anatomic region (Fig. 18-18). (See Chapter 83.) By localizing a mass to a particular region of the mediastinum,^{145,146} the differential diagnosis can be made more specific, and biopsy procedures can be planned with greater accuracy. In addition to the information gained from the location of the mass, the density discrimination of CT enables soft-tissue abnormalities, fluid collections, and fatty tissue (see Chapter 83 eFigure Image Gallery) to be distinguished accurately (Fig. 18-19).^{147–149} With use of intravenous contrast material, masses and vascular anomalies (see eFigs. 83-47B, 48B-D, 49B, and 50B-D) can be accurately delineated. CT is useful in further evaluating a mass initially detected on chest radiography, for demonstrating pathology that is suspected on the basis of the clinical setting (but not visible on conventional imaging studies), and for precisely delineating the location of lesions for planning therapy.

MRI may be indicated as the primary imaging modality in patients with suspected mediastinal mass in many situations: for determining whether mediastinal abnormalities are vascular, for displaying lesions at the thoracic inlet in the coronal plane, for distinguishing cystic from solid masses (see eFigs. 83-28 and 83-43C and D),¹⁵⁰ for detecting hemorrhagic components within a mediastinal lesion (see eFig. 83-36D and E), for distinguishing between surgical (see eFigs. 83-17D-G and 83-24C and D) and nonsurgical (see eFig. 83-16B-D) mediastinal masses,¹⁵¹ and for evaluation of posterior mediastinal masses (see eFig. 83-41D and E) and neurogenic tumors (see eFig. 83-15), which may have intraspinal components.^{150,152,153} Early experience with mediastinal MRI suggested that this modality may be capable of distinguishing between a tumor mass and a benign fibrous mass^{154–156} following radiation therapy,

Figure 18-19 Chest CT characterization of fatty mediastinal masses. **A**, Frontal chest radiograph shows a contour abnormality (arrows) along the right inferior mediastinum. **B**, Axial chest CT shows a fatty right paracardiac mass (arrows), consistent with thymolipoma. a distinction that can be difficult with CT. However, in practice, the differentiation of tumor from associated inflammation or post-treatment changes is difficult,^{154,155} and PET is generally preferred for this distinction.

MRI is rarely indicated for imaging hilar masses; CT is usually preferred for this application. Traditionally, contrast-enhanced MR would be considered as an alternative to contrast-enhanced chest CT for the assessment of hilar or mediastinal lesions in patients with impaired renal function, but recognition that, in patients with impaired renal function, gadolinium may predispose to fibrosing dermopathy, referred to as nephrogenic systemic fibrosis, gives pause to such an approach.¹⁵⁷ Nevertheless, unenhanced MR, due to its inherent high-contrast resolution (see eFig. 83-14), may still provide valuable information regarding hilar and mediastinal masses.

Primary and metastatic cardiac tumors usually are often detected initially by echocardiography, but MRI is also an accurate method of delineating such lesions.¹⁵⁸⁻¹⁶⁰ It is thus appropriate as a problem-solving technique for patients with inconclusive echocardiographic examinations, but it is also emerging as a first-line examination for a number of cardiovascular applications. Both MRI and CT can specifically demonstrate fat within cardiac lesions and fluid within pericardial cysts (see eFig. 83-43B-D). Intracardiac tumor

(Fig. 18-20) and thrombus frequently can be differentiated by MRI, particularly following contrast administration.

DIFFUSE LUNG DISEASE

The clinical assessment of a patient with suspected *diffuse interstitial lung disease* (DILD) can be a difficult and perplexing problem. Imaging studies are often important in reaching a final diagnosis, suggesting appropriate diagnostic procedures, and assessing the patient's course and prognosis.

In clinical practice, the imaging studies most frequently used to evaluate patients with suspected DILD are chest radiographs and HRCT. HRCT is typically used when the diagnosis is uncertain at chest radiography and clinical evaluation and further assessment is considered warranted, as well as to assess treatment response in patients with established diagnoses.

HRCT findings in a wide variety of parenchymal diseases have been described, including the idiopathic interstitial pneumonias,¹⁶¹ sarcoidosis,¹⁶²⁻¹⁶⁵ diffuse neoplasms, pneumoconioses,¹⁶⁶⁻¹⁷⁰ infections, and numerous other disorders.¹⁷¹⁻¹⁸³ These studies have shown that HRCT delineates both normal anatomic structures (Fig. 18-21) and pathologic alterations in lung morphology more clearly

Figure 18-21 Normal high-resolution chest CT (HRCT): lobular anatomy. **A** (**C**, inset detail image of the area of interest in the right lower lobe), Axial HRCT image through the level of the right lower lobe bronchus shows normal major (oblique) fissures, central airways, and pulmonary vessels. Small peripheral pulmonary veins (*small white arrowheads*) are visible. Pulmonary veins travel within interlobular septae and therefore may outline secondary pulmonary lobules (lung parenchyma between *small white arrowheads*). Occasionally the centrilobular artery (*small black arrows*), the arterial structure entering the center of the pulmonary lobule, may be normally visible. An understanding of secondary pulmonary lobular anatomy underlies the anatomic approach for localization of small nodules detected at HRCT, which provides the basis for differential diagnosis of such nodules. **B**, Illustration of the normal secondary pulmonary lobule. Pulmonary veins (*single arrowheads*), travel within interlobular septae (*double arrowheads*). The centrilobular artery and bronchus (*arrow*) enters the secondary lobule and branches sequentially, eventually extending to the level of gas exchange units—respiratory bronchioles, alveolar ducts, alveolar sacs, and alveoli and the capillary network associated with these structures. (**A** and **C**, Courtesy Michael Gotway, MD.)

than routine CT or chest radiographs.^{165,179,184,185} Much of the basis of HRCT interpretation rests on recognition of the anatomy of the secondary pulmonary lobule (see Fig. 18-21) as reflected on HRCT images; in particular, the histopathologic patterns of disease involvement of the secondary pulmonary lobule are often reflected in HRCT images, and recognition of the HRCT correlates of these disease facilitates noninvasive diagnosis. This approach is particularly useful for the anatomic localization of small nodules at HRCT, as will be illustrated subsequently.

In general, HRCT findings of lung disease can be divided into increased lung opacity, including reticular, linear, and nodular opacities, consolidation, and GGO, and decreased lung opacities such as cysts, cavities, emphysema, and mosaic perfusion.¹⁸⁶

Increased Lung Opacity

Linear and Reticular Opacities. Thickening of the interstitial fiber network of lung by fluid, fibrous tissue, or interstitial infiltration by cells results in an increase in both linear and reticular opacities as seen on HRCT.¹⁸⁶ Interlobular septal thickening is seen in patients with a variety of interstitial lung diseases, but most typically pulmonary edema, lymphangitic spread of tumor (Fig. 18-22),¹⁸⁶ and sarcoidosis,¹⁶⁴ in addition to a small number of rarer causes.^{169,187,188} Septal thickening is not common in patients with interstitial fibrosis, except for those with sarcoidosis and asbestosis.¹⁸⁹ Honeycombing reflects extensive fibrosis with lung destruction and results in a cystic, reticular appearance on HRCT that is characteristic (Fig. 18-23).^{186,189} When honeycombing is present, normal lung architecture is distorted and secondary lobules are difficult or impossible to recognize. The cystic spaces of honeycombing can range from several millimeters to several centimeters in diameter and are characterized by thick, clearly definable, fibrous walls and are often found stacked in several layers in the subpleural regions of lung.^{190,191}

Nodules. Nodules can be classified according to their distribution as perilymphatic, random, or centrilobular according to their distribution within the secondary pulmonary

Figure 18-22 This HRCT image in a patient with lymphangitic metastasis from breast carcinoma shows smoothly thickened interlobular septa (*arrowheads*); note asymmetry of the process. (Courtesy Michael Gotway, MD.)

Figure 18-23 HRCT at two levels shows rheumatoid lung disease with honeycombing. The appearance of multiple, contiguous, air-filled cystic structures having a subpleural predominance is typical. (Courtesy Michael Gotway, MD.)

lobule (see Fig. 18-21).^{186,192} Recognition of one of these distributions is fundamental to the generation of differential diagnoses.^{192,193} Perilymphatic nodules affect the peribronchovascular, interlobular septal, subpleural, and centrilobular interstitial compartments and are typical of sarcoidosis, which tends to have a peribronchovascular and subpleural predominance (see Fig. 18-24, Video 18-10)^{164,192-194}; silicosis and coal workers' pneumoconiosis, which predominate in the subpleural and centrilobular regions^{169,174,187}; and lymphangitic spread of tumor, which is usually peribronchovascular and septal.¹⁸⁶ Random nodules are most typical of miliary infections (see Fig. 18-25)¹⁹⁵ and hematogenous metastases.¹⁸⁶ Well-defined centrilobular nodules can be seen in silicosis and coal workers' pneumoconiosis,¹⁶⁷ asbestosis,¹⁶⁶ and Langerhans cell histiocytosis.¹⁹⁶ Poorly defined centrilobular nodules often reflect bronchiolar or peribronchiolar abnormalities¹⁹³ and can be seen in silicosis and coal workers' pneumoconiosis,¹⁶⁷ endobronchial spread of infection,¹⁹⁵ pulmonary

hemorrhage (see Fig. 18-26), hypersensitivity pneumonitis (see Fig. 18-27),^{197,198} and pulmonary edema.¹⁹⁹

Consolidation and Ground-Glass Opacity. Air space consolidation, by definition, is seen when alveolar air is replaced by fluid, cells, or other material.¹⁹¹ On HRCT, consolidation results in an increase in lung opacity associated with obscuration of underlying vessels. Among patients with chronic DILD, common causes of this pattern include chronic eosinophilic pneumonia and cryptogenic organizing pneumonia.^{200,201} The term GGO refers to a hazy increase in lung opacity that is not associated with obscuration of underlying vessels.¹⁹¹ This finding can reflect the presence of a number of diseases and can be seen in patients with either minimal interstitial thickening or minimal air space filling.^{178,180,202-205} It often reflects the presence of active disease, such as pulmonary edema (see eFig. 70-6G); alveolitis associated with some idiopathic interstitial pneumonias (see eFigs. 63-11C-F, 16, 17, 18, 20, 28, 26, and 29);

Figure 18-24 HRCT illustration of perilymphatic nodules: sarcoidosis. **A**, Axial HRCT image of a patient with sarcoidosis shows numerous subpleural nodules in relation to costal and fissural visceral pleural surfaces (single arrowheads), and nodules are also clearly visible along bronchovascular bundles (double arrowheads). These findings, along with the patchy distribution of the nodules, are diagnostic of sarcoidosis in the appropriate clinical setting. **B**, Perilymphatic nodule distribution in the secondary pulmonary lobule. Small nodules are primarily distributed along the visceral pleural surfaces (single arrowhead), interlobular septae, and bronchovascular bundles (double arrowhead). **C**, Anatomic localization of small nodules at HRCT. Perilymphatic nodules are primarily distributed along costal and fissural visceral pleural surfaces (single arrowheads), interlobular septae, and bronchovascular bundles (double arrowhead). (A, Courtesy Michael Gotway, MD.)

Figure 18-25 HRCT illustration of random nodules: miliary tuberculosis. **A**, Axial HRCT image shows numerous, small, circumscribed nodules equally distributed throughout the lungs bilaterally, with nodules seen in contact with fissural pleural surfaces, as well as sparing the fissural surfaces. **B**, Random nodule distribution in the secondary pulmonary lobule. Small nodules are seen along the bronchovascular bundles, interlobular septae, and visceral pleural surfaces. **C**, Anatomic localization of small nodules at HRCT. Random nodules are distributed along costal and fissural visceral pleural surfaces, interlobular septae, and bronchovascular bundles in a fairly even, diffuse distribution bilaterally. (A, Courtesy Michael Gotway, MD.)

Figure 18-26 HRCT illustration of centrilobular nodules: chronic pulmonary hemorrhage. **A**, Axial HRCT image shows numerous, bilateral, poorly defined ground-glass opacity nodules (arrows). Note that the nodules approach, but generally do not touch, costal and fissural visceral pleural surfaces; this relationship is particularly evident along the left major fissure. Also note that occasionally the relationship of the nodules to adjacent pulmonary veins (single arrowheads, right upper lobe) and interlobular septae (single arrowhead, left upper lobe) is apparent—the nodules have a small amount of “spared” lung separating them from the interlobular septae and small pulmonary veins, a key indicator of the centrilobular distribution. **B**, Centrilobular nodule distribution in the secondary pulmonary lobule. Small nodules are seen primarily in the center of the lobule, along the bronchovascular bundles, largely sparing the interlobular septae, pulmonary veins, and visceral pleural surfaces. **C**, Anatomic localization of small nodules at HRCT. Centrilobular nodules typically approach, but do not contact, the costal and fissural visceral pleural surfaces and interlobular septae. Centrilobular nodules may be round (single arrowhead) and solid, poorly defined and irregular in shape (arrow), or show ground-glass attenuation. When centrilobular nodules show branching configurations (double arrowhead), the nodule morphology is often described as “tree-in-bud” opacity. (A, Courtesy Michael Gotway, MD.)

Figure 18-27 HRCT illustration of centrilobular nodules: hypersensitivity pneumonitis. **A**, Axial HRCT image shows numerous, bilateral, poorly defined ground-glass opacity nodules (arrows). Note that the nodules approach, but generally do not touch, costal and fissural visceral pleural surfaces—this appearance is a key indicator of the centrilobular distribution. **B**, Centrilobular nodule distribution in the secondary pulmonary lobule. Small nodules are seen primarily in the center of the lobule, along the bronchovascular bundles, largely sparing the interlobular septae, pulmonary veins, and visceral pleural surfaces. **C**, Anatomic localization of small nodules at HRCT. Centrilobular nodules typically approach, but do not contact, the costal and fissural visceral pleural surfaces and interlobular septae. Centrilobular nodules may be round (single arrowhead) and solid, poorly defined and irregular in shape (arrow), or show ground-glass attenuation. When centrilobular nodules show branching configurations (double arrowhead), the nodule morphology is often described as “tree-in-bud” opacity. (A, Courtesy Michael Gotway, MD.)

pulmonary hemorrhage (see Fig. 18-26, see eFigs. 70-6C, eFigs. 67-1, 2E and F, 3C, 4, 5, 8B, 9B-E); infectious pneumonias (particularly *Pneumocystis jirovecii* pneumonia (see eFigs. 90-12B, 14C, 15B, 18, and 20B and C); lipid pneumonia (see eFig. 70-6B); alveolar proteinosis (see eFigs. 70-4 and 5, 8A-D, 9, and 10); hypersensitivity pneumonitis (see Fig. 64-4), often with a centrilobular nodular appearance (see Fig. 18-27, see eFigs. 64-2C and D, and 64-3C-E); and sarcoidosis.²⁰⁶ However, GGO may reflect the presence of fibrosis below the resolution of HRCT, particularly when the GGO is associated with other findings of fibrotic lung disease, such as coarse reticulation, architectural distortion, traction bronchiectasis, and honeycombing.²⁰³ Because of its potential reflection of active lung

disease, the presence of GGO may lead to surgical lung biopsy, depending on the clinical status of the patient.

Decreased Lung Opacity

Emphysema. Emphysema is accurately diagnosed with HRCT, and HRCT is more sensitive for the detection of emphysema than routine CT or chest radiographs.^{141,181} Emphysema results in focal areas of low attenuation that can be easily contrasted with surrounding, higher-attenuation, normal lung parenchyma (Fig. 18-28). In patients with centrilobular emphysema, areas of lucency can be seen surrounding the centrilobular artery and have a patchy, upper lobe distribution. In panlobular emphysema, focal areas of lucency are not usually present, but a

Figure 18-28 HRCT scans for emphysema. This HRCT is from a patient with panlobular emphysema who underwent right lung transplantation. The emphysematous left lung is easily contrasted with the normal-appearing right lung. The emphysematous left lung is less dense, is larger in volume, and contains fewer and smaller vessels. (Courtesy Michael Gotway, MD.)

diffuse simplification of lung architecture and a decrease in lung attenuation are present (see Fig. 18-28). In clinical practice, HRCT is rarely used in an attempt to diagnose emphysema. Usually, the combination of a smoking history, a low diffusing capacity, airway obstruction on pulmonary function tests, and an abnormal chest radiograph showing large lung volumes is sufficient to make the diagnosis. HRCT is useful for evaluating patients with COPD who are being considered as candidates for lung volume-reduction surgery. In addition, some patients with early emphysema can present with clinical findings more typical of infiltrative lung disease or pulmonary vascular disease, namely shortness of breath and low diffusing capacity, without evidence of airway obstruction on pulmonary function tests.²⁰⁷ In such patients, HRCT can be valuable for detecting the presence of emphysema and excluding an interstitial abnormality. If significant emphysema is found on HRCT, no further evaluation is necessary.²⁰⁸

Cystic Pulmonary Diseases. Lymphangioleiomyomatosis (see images associated with Chapter 69, eFig. 56-2, and Fig. 18-29) and Langerhans cell histiocytosis often result in multiple lung cysts (see Fig. 69-3B), which have a distinct appearance on HRCT.^{196,209-215} The cysts have a thin but easily discernible wall, ranging up to a few millimeters in thickness. Associated findings of fibrosis are usually absent or much less conspicuous than they are in patients with honeycombing. In these diseases, the cysts are usually interspersed within areas of normal-appearing lung. In patients with Langerhans cell histiocytosis (see Fig. 69-3B and eFig. 54-37), the cysts can have bizarre shapes and an upper lobe predominance. Numerous causes of cystic and cavitary pulmonary lesions are recognized.²¹⁶

Mosaic Perfusion. Decreased lung attenuation not reflecting the presence of cystic lesions or emphysema can sometimes be recognized on HRCT in patients who have diseases that produce air trapping, poor ventilation, or poor perfusion.^{181,200,202,204-208,211-213,217,218} The areas of decreased

Figure 18-29 HRCT for cystic lesions. An HRCT in a patient with lymphangioleiomyomatosis shows the multiple cystic areas, which have clearly definable walls, in contrast to the appearance of emphysema (see Fig. 18-28). (Courtesy Michael Gotway, MD.)

Figure 18-30 HRCT for mosaic perfusion. HRCT in a patient with cystic fibrosis shows inhomogeneous opacity in the lung bases bilaterally, somewhat geographically distributed. The areas of decreased attenuation represent mosaic perfusion in this patient resulting from a combination of regional air trapping due to large airway disease and hypoperfusion in the affected areas of lung. (Courtesy Michael Gotway, MD.)

lung attenuation that are seen on HRCT can be focal, lobular,²¹⁹ lobar, or multifocal. The term *mosaic perfusion* has been used to refer to patchy decreased lung attenuation resulting from perfusion abnormalities (Fig. 18-30).¹⁹¹ In patients with air trapping, this appearance can be enhanced with expiratory HRCT.^{181,218,220,221}

Diagnostic Utility

The utility of chest radiographs and HRCT in the clinical diagnosis of diffuse lung disease relates to their ability to detect the presence of lung disease (sensitivity and specificity), characterize its nature, assess disease activity, and guide lung biopsy.

Sensitivity and Specificity. It is well documented that chest radiographs are limited in both their sensitivity and specificity in patients with DILD.²²²⁻²²⁴ For example, Gaensler and Carrington²²³ reported that nearly 16% of patients with pathologic proof of interstitial lung disease had normal

chest radiographs. The sensitivity of CT for detecting lung disease has been compared with that of chest radiography in a number of studies; without exception, these have shown that CT, and particularly HRCT, is more sensitive than chest radiography for detecting both acute and chronic diffuse lung diseases.^{163,170,175,197,225,226} The average results of several studies show that the sensitivity of HRCT for detecting DILD is approximately 94% compared with 80% for chest radiographs.²²⁴ The sensitivity of HRCT has also proved superior to that of routine CT obtained with wider collimation.^{166,205,206}

It is important to note that the increased sensitivity of HRCT is not achieved at the expense of decreased specificity or diagnostic accuracy.^{171,174,224} A specificity of 96% for HRCT compared with 82% for chest radiographs was reported by Padley and colleagues²²⁴ in patients with DILD. In other studies of patients with suspected DILD on chest radiographs, normal biopsy results have been proven in 10% to 20% of patients.^{222,223} Although HRCT is clearly more sensitive than chest radiographs, its sensitivity in detecting lung disease is not 100%, and a negative HRCT cannot generally be used to rule out DILD. For example, in one study, although HRCT had high sensitivity and specificity values, 4% of subjects with biopsy-proven lung disease were interpreted as having a normal HRCT.²²⁴

Diagnostic Accuracy. Even in the presence of definite abnormalities, chest radiographs have limited diagnostic accuracy for patients with DILD.²²⁷ Numerous reports have shown that HRCT is significantly more accurate than are chest radiographs in diagnosing both acute and chronic diffuse lung disease, usually allows a more confident diagnosis, and is subject to considerably less interobserver variation in its interpretation.^{171,173,174,181,189,205,228-234}

In an attempt to refine diagnostic accuracy, Grenier and coworkers¹⁷² used Bayesian analysis to determine the relative value of clinical data, chest radiographs, and HRCT for patients with chronic DILD. For this study, two samples from the same population of patients with 27 different diffuse lung diseases were consecutively assessed: an initial retrospectively evaluated set of “training” cases ($n = 208$) and a subsequent prospectively evaluated set of “test” cases ($n = 100$) for validation. The results showed that for the test group an accurate diagnosis could be made in 27% of cases based on clinical data only, increasing to 53% ($P < .0001$) with the addition of chest radiographs and to 61% ($P = .07$) with the further addition of HRCT scans. In some situations, HRCT findings are sufficiently diagnostic to obviate biopsy.^{161,186,235} In particular, the presence of an HRCT pattern typical of usual interstitial pneumonia/idiopathic pulmonary fibrosis, seen in more than 50% of patients suspected of this disorder, is sometimes sufficient to bypass surgical lung biopsy when encountered in the context of typical clinical features.^{190,235,236}

Assessing Disease Activity. In addition to being more sensitive, specific, and accurate than chest radiographs, HRCT may also play a critical role in the evaluation of disease activity in patients with diffuse lung disease.^{161,186,235} Available data suggest that, in certain cases, HRCT may be used to determine the presence or absence, and extent, of reversible (acute or active) lung disease compared with

irreversible (fibrotic) lung disease. Furthermore, because HRCT may accurately identify subtle “active” lung disease, it can be used to study patients who are being treated in order to monitor the success or failure of the treatment.^{161,162,186,235,237-240}

Although a number of HRCT findings have been described as being indicative of active or reversible lung disease in patients with different disease entities, most attention has focused on the potential significance of GGO in patients with chronic DILD.^{178,203} This finding has been reported in a wide range of DILDs, including usual interstitial pneumonia, desquamative interstitial pneumonitis, lymphoid interstitial pneumonia, sarcoidosis, hypersensitivity pneumonitis, alveolar proteinosis, cryptogenic organizing pneumonia, respiratory bronchiolitis, and chronic eosinophilic pneumonia.¹⁷⁸ GGO has also been described in patients with premalignant lesions and pulmonary neoplasms, in particular atypical adenomatous hyperplasia and adenocarcinoma in situ (formerly referred to as *bronchoalveolar carcinoma*), respectively, as well as a wide variety of acute lung processes, such as acute interstitial pneumonia; bacterial, fungal, viral, and parasitic infections; pulmonary hemorrhage syndromes; and congestive heart failure and other causes of pulmonary edema.

Although GGO is a nonspecific finding and can reflect various histologic abnormalities, in patients with chronic DILD, GGO may represent active parenchymal inflammation. In a study of 26 patients with DILD in whom histopathologic correlation was obtained, biopsy specimens demonstrated that GGO corresponded to inflammation in 24 cases (65%), and in 8 additional cases (22%), inflammation was present but fibrosis predominated.^{178,203} In only 5 cases (13%) was fibrosis the sole histologic finding. Similarly, Leung and associates,²⁰² in a study of 22 patients with a variety of chronic DILDs and evidence of GGO as either a predominant or an exclusive HRCT finding, showed that 18 (82%) had potentially active disease identified on lung biopsy.

GGO may also be seen in the presence of interstitial fibrosis without active inflammation.^{178,202,203} For GGO to indicate active disease, this finding should generally be unassociated with HRCT findings of fibrosis.^{178,202,203} In patients with idiopathic pulmonary fibrosis, a significant correlation has been found between the presence of HRCT findings of GGO and pathologic findings of active inflammation, the development of pulmonary fibrosis, the patient's prognosis,^{182,237,238,240-247} and the likelihood of response to therapy.^{237,238,240} HRCT has also been used to assess disease activity, as well as the likelihood of response to therapy in patients with sarcoidosis.^{162,165,194,204,239} In most series of patients with sarcoidosis, the main HRCT determinant of disease activity has been the presence and, to a lesser degree, the extent and distribution of small nodules.^{165,204}

Guiding Lung Biopsy. Among the many indications for HRCT, an important one is as a potential guide for surgical lung biopsies. Many “diffuse” lung diseases are quite patchy in distribution, with areas of abnormal lung frequently interspersed among relatively normal areas of lung parenchyma. Furthermore, both active and fibrotic disease can be present in the same lung.^{142,144,161,182,186,194,199-201,235,246,247} To establish a specific diagnosis and assess the clinical

Figure 18-31 Chest CT for airway lesions. **A**, Axial CT image shows a squamous carcinoma occluding the right middle lobe bronchial orifice (*large arrow*), producing complete collapse of the right middle lobe. Low-attenuation tubular foci (*small arrows*) visible within the collapsed right middle lobe represent mucus-impacted bronchi. **B**, Bronchoscopic image shows the carcinoma occluding the right middle lobe bronchus and protruding into the bronchus intermedius (*arrows*). (Courtesy Michael Gotway, MD.)

significance of the abnormalities present, it is critically important to sample those portions of the lung that are the most abnormal and the most likely to be active. Optimal sampling sites can be selected with HRCT. Also, as a direct consequence of its ability to visualize, characterize, and determine the distribution of parenchymal disease, HRCT also provides a unique insight into the likely efficacy of transbronchial or surgical lung biopsy in patients with either acute or chronic diffuse lung disease. Surgical lung biopsy is often diagnostic, with accuracies greater than 90% generally reported,^{186,223,235,248,249} but this procedure is also subject to sampling error. HRCT is of considerable value in determining the most appropriate sites for biopsy.^{161,186,229,235}

INTRATHORACIC AIRWAY DISEASE

Previously, CT was used to evaluate the trachea or central airways, but HRCT is currently more appropriate for imaging the peripheral airways. With the development of MSCT, volumetric HRCT is now possible, which allows simultaneously optimized evaluation of the central airways combined with HRCT technique for evaluation of the peripheral airways in a single examination.¹⁹⁰

Central Airways

CT can effectively evaluate lesions (Fig. 18-31) of the trachea and central airways,²⁵⁰ including strictures and stenoses, inflammatory diseases such as polychondritis (Fig. 18-32), some cases of extrinsic versus intrinsic obstruction,²⁵¹ aspirated foreign objects, tracheobronchomalacia, and neoplasms (Video 18-11).²⁵⁰ MS CT, with its ability to acquire images rapidly with equal resolution in all planes, is particularly useful in this assessment and can provide detailed three-dimensional analysis of the central airways (Video 18-11B). The ability to produce excellent quality three-dimensional images aids in the evaluation of subtle airway stenoses and complex airway lesions, particularly when they are oblique with respect to the imaging plane. In the assessment of tracheal and central bronchial neoplasms, CT does not substitute for bronchoscopy and biopsy, but it can be useful to determine the extent of invasion and to direct the bronchoscopist to a particular

Figure 18-32 Multislice CT for central airway evaluation. With rapid volumetric high-resolution imaging, MSCT allows detailed three-dimensional analysis of the airways. In a patient with relapsing polychondritis, coronally reconstructed image shows diffuse thickening and narrowing of the trachea. (Courtesy Michael Gotway, MD.)

segment or to a precise location of peribronchial disease. The major value of CT imaging is its ability to visualize the luminal contents, the airway wall, and the surrounding soft tissue. Accordingly, the use of CT carries the greatest benefit in circumstances that require all three of these capabilities.

Bronchiectasis

CT should be the initial investigation in all patients with suspected bronchiectasis, as discussed further in Chapter 48.²⁵²⁻²⁵⁵ The sensitivity and specificity of HRCT (scans at 1-mm intervals) for diagnosing bronchiectasis to the segmental level are 95% to 98% (Fig. 18-33), whereas the sensitivity and specificity of thick-section CT are only about 80%. In current medical practice, CT has replaced bronchography, and a review of the CT criteria for diagnosing bronchiectasis and the technical pitfalls that may be encountered has been published.²⁵⁶ MSCT scanning with narrow collimation (on the order of 1 mm) provides a larger volume of coverage with spatial resolution superior to routine single-slice spiral CT yet also allows for volumetric imaging and the creation of exquisite reformatted images, including volume rendering.

Figure 18-33 Normal appearance of bronchi at chest CT compared with bronchiectasis. **A** and **B**, Axial chest CT images show the appearance of normal peripheral bronchi—the internal diameter of the bronchus (arrows) is similar to the adjacent pulmonary artery (arrowheads), and the bronchi are patent and uniformly thin-walled. **C** and **D**, Detailed images through the lung bases showing CT features of bronchiectasis and large airway disease. The bronchi are abnormally dilated—the internal diameter of the bronchi (arrows) clearly exceeds the size of the adjacent pulmonary arteries (single arrowheads). The bronchi are also clearly visualized more peripherally than is normal (compare with **A** and **B**, where peripheral bronchi are largely not visible). Finally, the bronchi (arrows) are visibly thick-walled, and several airways show intraluminal secretions and impaction (double arrowheads). (Courtesy Michael Gotway, MD.)

Small Airway Disease

HRCT has the ability to demonstrate abnormalities of small airways having a diameter of a few millimeters or less.^{161,193,199,200,218,220,221,235,257} Abnormalities that can be diagnosed include (1) inflammatory forms of bronchiolitis, such as cellular bronchiolitis (usually due to infection [Fig. 18-34A], aspiration, or hypersensitivity pneumonitis [see Figs. 18-27 and 18-34B]), respiratory bronchiolitis (Fig. 18-34C), follicular bronchiolitis, and panbronchiolitis (Fig. 18-34D); and (2) small airway diseases associated with airflow obstruction (e.g., constrictive bronchiolitis [Fig. 18-34E and F]).²⁵⁷ Cryptogenic organizing pneumonia has been previously classified as a disease of the small airways but is now considered an idiopathic interstitial pneumonia.^{161,235,257} The use of postexpiratory HRCT is particularly important in the diagnosis of small airway diseases because air trapping may be visible in the absence of other abnormalities (see eFig. 106-3).^{220,221} Postexpiratory HRCT may be performed by imaging after a forced vital capacity maneuver (Video 18-12, see Videos 106-1 and 106-3)²⁵⁸ or with lateral decubitus CT.²⁵⁹ Available data suggest that postexpiratory CT performed during a forced vital capacity maneuver, called “dynamic expiratory CT,” is a more effective technique for the demonstration of subtle or transient air trapping.^{258,260,261}

CARDIOVASCULAR DISEASE

Pulmonary Thromboembolism

Chest MSCT, performed with intravenous contrast injection using a specific CT pulmonary angiography (CTPA) technique, has emerged as the test of choice for the imaging evaluation

of suspected pulmonary embolism. Ventilation-perfusion scanning has long been used as the initial test for such patients. Its strengths and its limitations are well known and reviewed in Chapter 57. The test is extremely safe, widely available, and exceedingly sensitive: a normal perfusion scan effectively excludes pulmonary embolism. A high-probability scan is quite specific (97% in the *Prospective Investigation of Pulmonary Embolism Diagnosis* [PIOPED] I study).²⁶² However, a substantial fraction of perfusion scans yield results that are abnormal but nonspecific. In addition, it has been recognized increasingly that imaging the lower-extremity veins can be useful and cost-effective for many patients suspected of having acute pulmonary embolism; thus, a single imaging procedure that evaluates both the lower extremity veins and the pulmonary arteries would be quite useful. Owing to these considerations, improved CTPA techniques are being increasingly used to diagnose pulmonary thromboembolism.

Single-slice spiral CTPA, in pooled data from a number of studies, showed an overall sensitivity and specificity approaching 90% and 96%, respectively. Regardless, criticisms regarding the methodology employed in single-slice CTPA studies, as well as the long-held faith in the diagnostic accuracy of catheter pulmonary angiography for suspected pulmonary embolism, led to relatively slow adoption of the use of CTPA for this application in some centers. Once MSCT technology became available, however, it became clear that multislice CTPA scans could demonstrate smaller vessels and therefore, by inference, should be more sensitive than single-slice CTPA for the detection of thromboembolic disease. Several studies investigating the incremental value of multislice CTPA over single-slice CTPA for the diagnosis of thromboembolic disease (Fig. 18-35A, Video 18-13) 

Figure 18-34 HRCT manifestations of small airway disease. **A**, Bronchopneumonia and bronchiolitis. Axial chest CT image through the right lower lobe shows numerous small, solid centrilobular nodules (*arrow*), some with branching configurations (*arrowhead*), the latter consistent with “tree-in-bud” opacity, representing bronchiolar impaction. Compare with diagrams in *Figs. 18-26* and *18-27*. **B**, Cellular bronchiolitis in hypersensitivity pneumonitis. Axial chest CT image through the right lower lobe shows poorly defined ground-glass opacity centrilobular nodules (*arrowheads*). Areas of lobular low attenuation (*arrows*), representing air trapping resulting from inflammatory bronchiolitis, are present. **C**, Respiratory bronchiolitis. Axial chest CT image through the right upper lobe shows faintly detectable ground-glass attenuation nodules (*arrowheads*). **D**, Panbronchiolitis. Axial chest CT image through the right lower lobe shows large airway thickening and dilation (*arrows*), associated with intraluminal material and small airway impaction (*arrowhead*). **E** and **F**, Constrictive bronchiolitis (bronchiolitis obliterans). Axial chest CT image through the left lung shows normal inspiratory scan findings (**E**). Postexpiratory imaging (**F**) shows the development of numerous areas of low attenuation consistent with air trapping, in some areas with a lobular configuration (*arrows*), due to small airway obstruction. (Courtesy Michael Gotway, MD.)

were conducted shortly after the introduction of this technology, including the PIOPED II trial,²⁶³ the results of which were published in 2006. In PIOPED II, the sensitivity of multislice CTPA for the diagnosis of pulmonary embolism was 83% (95% confidence limits, 76% to 92%) and the specificity was 96%. The positive predictive value of a positive multislice CTPA study was 86%, and the negative predictive value was 95%. The sensitivity of multislice CTPA in

the PIOPED II trial has led some investigators to question the utility of CTPA for the evaluation of suspected pulmonary embolism; currently, however, multislice CTPA is widely used as the first-line diagnostic modality for the investigation for such patients all across the world.

Ultimately, the main question that must be answered when patients suspected of thromboembolic disease undergo CTPA is, “Can anticoagulation be safely withheld

Figure 18-35 CT pulmonary angiography (CTPA) and indirect CT venography images demonstrate pulmonary emboli and deep vein thrombosis. **A**, CTPA shows bilateral large filling defects (arrows) consistent with pulmonary emboli. **B** and **C**, Axial indirect CT venography (i.e., without additional contrast material injection) shows filling defects in the right common femoral and iliac veins (arrowheads) consistent with venous thrombi. (Courtesy Michael Gotway, MD.)

Figure 18-36 MRI demonstrates pulmonary embolism and deep vein thrombosis. **A**, This magnetic resonance angiogram (MRA) image shows a filling defect consistent with pulmonary embolus in the left lower lobe artery (arrow). **B**, This MR image made without contrast material shows a filling defect in the right superficial femoral vein consistent with venous thrombus (arrow), whereas the contralateral vein is patent and without filling defects. (Courtesy Michael Gotway, MD.)

in patients with a negative result?” In other words, what is the negative predictive value of CTPA for thromboembolic disease? Several studies have addressed this question, and the negative predictive value of CTPA ranges from 95% to 99%.^{263,264} Importantly, it has been suggested that further diagnostic testing should be pursued when CTPA results (with or without indirect CT venography, see later) are discordant with the clinical probability for pulmonary embolism, particularly when CTPA results are negative and the clinical probability of pulmonary embolism is considered high.²⁶³

Various investigations also suggest that CTPA may also be able to detect deep venous thrombosis in the proximal leg and pelvic veins without injection of additional contrast material (Fig. 18-35B and C), a technique known as indirect CT venography.²⁶⁵⁻²⁶⁷ The addition of CT venography to CTPA studies obtained for the evaluation of suspected pulmonary embolism allows for the simultaneous evaluation of deep venous thrombosis and pulmonary embolism with a single test. Combining CTPA with CT venography increased the sensitivity for the diagnosis of pulmonary embolism to 90%, and the negative predictive value of the combination of the examinations was 97% in the PIOPED II trial.²⁶³

As for CTPA, MRI can demonstrate pulmonary embolism directly as intravascular filling defects on cross-sectional images (Fig. 18-36 and Video 18-14).²⁶⁸⁻²⁸⁰ Experience with MRI in patients suspected of having pulmonary embolism is far more limited than that with CTPA. The two techniques are probably overall roughly similar in accuracy for the detection of pulmonary embolism, although MRI may show more pronounced interobserver variability than CTPA and may show slightly decreased sensitivity compared with CTPA at the segmental and subsegmental vascular levels.²⁷⁸ The diagnostic accuracy of MRI for pulmonary embolism assessment is enhanced through the use of multiparametric protocols that include a combination of real-time steady-state free precession imaging, perfusion imaging, low flip angle, three-dimensional gradient-echo imaging, and contrast-enhanced MRA (see Video 18-14).^{268,269,272,275,276;} not all studies reporting the diagnostic accuracy of MRI for acute pulmonary embolism diagnosis have used a multiparametric approach.²⁷⁸ In addition, MRI has been shown to be highly accurate for detecting deep venous thrombosis.^{281,282}

The potential advantages of MRI are the lack of need for iodinated contrast material or ionizing radiation, ability to

Figure 18-37 Chest CT for pleural disease. Chest CT performed in a patient with a history of tuberculosis shows pleural thickening and calcification (arrows) and a residual pleural effusion (Ef) indicative of empyema. (Courtesy Michael Gotway, MD.)

Figure 18-38 Chest CT for pleural disease. A patient with prior asbestos exposure has focal areas of pleural thickening or pleural plaques within the left hemithorax (arrows). Pleural thickening on the right is associated with pleural effusion. This reflected the presence of early malignant mesothelioma. (Courtesy Michael Gotway, MD.)

image the pulmonary arteries and deep venous system in a single examination, ability to assess right ventricular function simultaneously, and ability to perform perfusion imaging. The latter point is of particular significance in light of the imperfect sensitivity of CTPA. The advantages of CTPA are higher spatial resolution, wider availability, fewer artifacts, faster examination time, and simpler, more robust technology, as well as, importantly, the availability of alternative diagnoses for patients with negative results. Currently, CTPA is a realistic option in the clinical management of patients with suspected pulmonary embolism; the clinical use of MRI is limited to medical centers with personnel who are highly skilled with advanced MRI technology.²⁷⁸

See the online version of this chapter for additional discussions on imaging acquired aortic diseases and congenital anomalies of the thoracic great vessels.

PLEURAL DISEASE

Most pleural processes, as discussed further in Chapters 79 to 82, can be imaged accurately and cost-effectively with conventional radiography or ultrasonography. However, CT, including single-slice spiral, multislice, and high-resolution, can be useful in evaluating several clinical problems relating to the pleura.^{102,296,297} These include differentiation of pleural and parenchymal disease (including the distinction between lung abscess and empyema); detection of subtle pleural abnormalities (such as early pleural plaques or small pneumothoraces); location of pleural fluid collections and pleural tumors, including localization for interventional purposes (e.g., tube drainage, biopsy); determination of the extent of pleural tumors (in particular, metastases and mesothelioma); and occasionally, characterization of pleural lesions (Figs. 18-37, 18-38, and Fig. 18-11) or paradiaphragmatic lesions. MRI currently has a limited role in the evaluation of pleural abnormalities.

Type of Fluid

Most effusions are near to water in attenuation; accordingly, CT numbers cannot be used to predict the specific

gravity of the fluid or its cause. One exception, however, is acute or subacute hemothorax. Hemothorax can sometimes appear inhomogeneous in attenuation, with some areas having an attenuation value higher than that of water.

The presence of pleural thickening is often of value in predicting the nature of the effusion. In patients with effusion (see Chapter 79), the presence of pleural thickening on CT indicates that the effusion is an exudate.¹⁰² By definition, the pleura is considered thickened if it is visible on a contrast-enhanced or unenhanced CT. Transudates are not associated with pleural thickening. Conversely, the absence of pleural thickening on contrast-enhanced CT is less helpful. In this case, the effusion can be an exudate or transudate. Only about 60% of exudates are associated with visible pleural thickening. However, the absence of pleural thickening on a contrast-enhanced scan rules out empyema; empyema is always associated with parietal pleural thickening on contrast-enhanced CT.

Pleural versus Parenchymal Disease

Opacities detected at chest radiography can frequently be localized as either parenchymal or extraparenchymal (pleural or chest wall) in location. Chest radiographic features that favor a parenchymal location for a pulmonary opacity include a relative rounded contour; relatively acute angles between the opacity and the chest wall (Fig. 18-39, see eFigs. 33-4B-E, 13B and C, and 26B and C), and air-fluid levels (when present) that are relatively similar in length in both frontal and lateral projections (Fig. 18-40). In contrast, opacities that are extraparenchymal in location often show an elliptical or lenticular contour; the opacity forms obtuse angles at the point of contact with the chest wall (see Fig. 18-39), and air-fluid levels commonly show significantly different lengths in the frontal and lateral projections (see Fig. 18-40). However, occasionally chest radiography may not be able to distinguish between parenchymal disease, pleural disease, and pathology affecting both compartments. CT can be useful in this setting. Pleural lesions

Acquired Aortic Disease

Acquired aortic diseases, such as aortic dissection, can be imaged with aortography, CT aortography, echocardiography, and MRI.^{283,284} Transthoracic echocardiography can assess the ascending aorta, but its limited field of view restricts its utility. Transesophageal echocardiography has produced definitive results,²⁸⁵ but this technique requires sedation and carries the risk of esophageal injury. Catheter aortography has previously been considered the standard method for demonstrating aortic dissection, but it is invasive and can produce both false-positive and (more commonly) false-negative results.²⁸³ It has largely been replaced by cross-sectional imaging methods for the evaluation of aortic pathology.

CT aortography can accurately identify the intimal flap, the true and false lumens (eFig. 18-38), the vessels involved by dissection, and the presence of end-organ perfusion impairment; thus, CT aortography is used routinely for evaluating aortic dissection.²⁸⁶ Complications of dissection, such as mediastinal hematoma, hemothorax, and hemo-pericardium, can also be detected. Limitations of CT aortography include the need for iodinated contrast material and its limited ability to assess aortic valve function (information that some surgeons require and others do not). The latter concern has been alleviated somewhat with the development of retrospectively electrocardiographic-gated CT aortography. With this technique, the imaging acquisition is conducted simultaneously with the electrocardiographic tracing, and data can then be reconstructed at any time during the cardiac cycle. Images reconstructed during late diastole often are motion free and allow assessment of the coronary arteries and aortic valve (eFig. 18-39).

MRI has several advantages in suspected aortic dissection. No iodinated contrast material is required (eFig. 18-40), and MRI does not require ionizing radiation. Fast gradient-echo and steady-state free precession MRI sequences can assess aortic valve and left ventricular function. However, MRI also has limitations in the assessment of dissections. Some patients are excluded from MRI for safety reasons. MRI examinations usually require more time than CT aortography studies for dissection. Artifacts lead to nondiagnostic studies more often with MRI than with CT aortography. Greater experience is required to interpret MR images accurately.

The relative accuracy of aortography, transesophageal echocardiography, CT aortography, and MRI for detecting and characterizing dissections has not been established by definitive prospective clinical trials. For practical reasons, such a trial is not likely to be conducted. Accordingly, which technique is superior is arguable, and judgment is required for individual cases. Aortography is the time-tested gold standard, but it is invasive and known to be inaccurate, particularly in cases with thrombosed false lumina, and has largely been replaced by cross-sectional methods. Extensive data indicate that both CT aortography and MRI are accurate in evaluating dissections.^{286,287} Our experience is that CT aortography and MRI have equivalent accuracy for detecting dissection and that both are more sensitive than aortography. However, no single technique always fulfills all of the requirements for characterization of dissections. Several reports suggest that hemodynamically unstable

patients with suspected aortic dissection should be studied with transesophageal echocardiography, whereas stable patients should be evaluated by CT aortography or MRI.^{285,288} MRI is also recommended for serial studies of patients with chronic dissection.

Both CT aortography and MRI have advantages over aortography for evaluating thoracic aortic aneurysms. Both are noninvasive, can document that a mediastinal mass is an aneurysm, can assess the thickness of the aortic wall, and can measure accurately the diameter and longitudinal extent of the aneurysm.²⁸⁶ In most situations, CT aortography is sufficient for diagnosis, and because it is less expensive and faster than MRI, it is the preferred study. MRI is particularly useful for patients with contraindications to iodinated contrast material.

In suspected traumatic aortic rupture, CT aortography has replaced catheter aortography for initial diagnosis.²⁸⁹ Catheter aortography is generally reserved for indeterminate CT aortography studies, problem-solving cases, or percutaneous interventional therapy, such as during endovascular stent placement. Although MRI has been reported in this setting, it is not normally used because the problems of monitoring and sustaining the trauma patient are greater with MRI; in addition, CT aortography examinations are substantially faster than MR examinations, and time is of the essence in traumatically injured patients. Chronic pseudoaneurysms (eFig. 18-41) in survivors of traumatic or iatrogenic aortic injury can be evaluated with either MRI or CT aortography.

Congenital Anomalies of the Thoracic Great Vessels

Echocardiography, MRI, and angiography are commonly chosen modalities for demonstrating great vessel anomalies, associated cardiac malformations, and their physiologic sequelae in children. CT angiography usefully can demonstrate simple vascular anomalies, such as an aberrant subclavian artery and persistence of the left superior vena cava. The vascular supply of sequestrations can be identified by MRI or CT angiography, and angiography is rarely necessary (see eFig. 18-18). In adults with congenital anomalies of the great vessels, MRI is often the procedure of choice because its field of view is wider than that of echocardiography and it is noninvasive but, in complex lesions, these techniques often are complementary. CT angiography is also an effective tool for the investigation of adult and pediatric congenital cardiovascular abnormalities.

Published experience with MRI in developmental anomalies of the great vessels has focused on aortic coarctation and pulmonary artery obstruction, but extensive investigations of the utility of MR techniques for other vascular abnormalities, including extracardiac shunts and partial anomalous pulmonary venous return, have been performed. Coarctation is detected accurately by MRI (eFig. 18-42) or CT angiography. Complications of treatment, including restenosis and aneurysm, can be detected,^{290,291} and the degree of collateral vascular supply, which affects the risk of surgery, can be established with either technique. The pressure gradient across the coarctation and the relative increase in blood flow distal to the coarctation

may be quantified by MRI. Such calculations also provide quantitative data regarding the efficacy of operative and percutaneous interventions.

MRI is the noninvasive imaging procedure of choice for detecting central pulmonary artery obstruction,²⁹² evaluating the potential for palliative shunts,²⁹³ and assessing the

results of surgery,^{290,294,295} although CT angiography is also highly useful. Comparisons of MRI with transthoracic echocardiography usually have shown MRI to be superior for demonstration of great vessel anomalies. Diagnosis of a variety of other congenital vascular anomalies by MRI and MSCT angiography also has been reported.

Figure 18-39 Chest radiographic localization of an opacity as parenchymal or extraparenchymal: angle of the opacity with the chest wall. **A**, Illustration showing the typically *acute* angles (arrowhead) formed by a parenchymal process, such as a lung abscess, with the chest wall, compared with the *obtuse* angles (arrow) usually formed with the adjacent chest wall by an *extraparenchymal* process, such as empyema. **B**, Frontal chest radiograph in a patient with a lung abscess shows the typically *acute* angles (arrowheads) formed with the chest wall by a *parenchymal* process. **C**, Frontal chest radiograph in a patient with empyema shows the usual *obtuse* angles (arrow) formed with the chest wall by an *extraparenchymal* process. (B and C, Courtesy Michael Gotway, MD.)

typically have obtuse tapering margins and sharp interfaces with adjacent lung parenchyma (see eFig. 33-7B-E), whereas parenchymal lesions tend to blend with lung parenchyma and have acute, irregular margins (see eFigs. 33-4B-E, 13A, and 26A). One of the more common and therapeutically important problems in this category is differentiating lung abscess from empyema. Empyemas typically have smooth outer and inner margins, a lenticular shape, and a sharp interface with underlying lung; they tend to displace pulmonary vessels around them (see eFig. 33-7B-E) and often display prominent rim enhancement (the “split pleura sign”) with intravenous administration of iodinated contrast material. Lung abscesses are characterized by spherical or polygonal shape, a thick wall with a shaggy or irregular inner margin, and permeation between adjacent pulmonary vessels (see eFigs. 33-4B-E, 12B and C, 26B and C). None of these features is unique, but when considered together, they permit categorization of the abnormality in most cases.

Early Detection

The contrast resolution and cross-sectional format of CT make it highly sensitive and accurate in detecting pleural thickening and early pleural plaques in patients with asbestos-related pleural disease (see Fig. 18-38).^{166,297} Circumscribed plaques often are overlooked on chest radiographs unless they are calcified or attain a thickness of about 5 mm or more. Furthermore, normal extrapleural soft tissues and fat can be misinterpreted as plaques when they are prominent on chest radiography. Both standard CT and HRCT are accurate for detecting pleural plaques, but HRCT may be more accurate for characterizing subtle plaques.

CT has been shown to be accurate and more sensitive than conventional radiographs in detecting pneumothoraces. This can be of particular importance in trauma patients, who may require intubation and positive-pressure ventilation.

Key Points

- After the medical history and physical examination, radiography is the most commonly used technique in the evaluation of patients with known or suspected thoracic disease.
- High-quality frontal and lateral chest radiographs can address many clinical questions. Currently available techniques of digital recording of images offer many interpretive and logistical advantages.
- Spiral (or helical) CT technology allows the entire chest to be scanned during a single breath-hold thereby permitting *volumetric* imaging, which generates a continuous block of data (rather than slices) that can be reconstructed to produce images in different slice thicknesses or orientations. Multislice CT uses *multiple* channels during the spiral acquisition, thereby dramatically increasing the amount of data acquired and the speed of acquisition.
- Multislice CT, with its rapid acquisition time and greatly improved resolution, has become the imaging method of choice for further evaluation of pulmonary nodule(s), lung cancer, mediastinal abnormalities, diffuse lung diseases, airway diseases, and suspected pulmonary embolism.
- Radiation is a relatively weak carcinogen, and the risk for radiation-induced carcinogenesis from a CT scan is generally far less than the information gained from an appropriately indicated study.
- *Magnetic resonance imaging* (MRI) is useful in evaluating superior sulcus lesions, brachial plexopathy, and certain cardiac and mediastinal abnormalities. MRI is also useful, though less often used than multislice CT, for evaluating suspected aortic dissection and pulmonary embolism.
- Further information about the application of imaging techniques and the results of these studies is presented in the chapters concerning specific pulmonary diseases that appear later in this book.

Figure 18-40 Chest radiographic localization of an opacity as parenchymal or extraparenchymal: differential air-fluid length. **A**, Frontal and **B**, lateral chest radiograph in a patient with lung abscess (same patient as eFig. 33-13A) shows an opacity with an air-fluid level (*line*) that is roughly the same length in both the frontal (**A**) and lateral (**B**) projections. The typical acute angle formed by the parenchymal process with the chest wall (*arrowhead*) is evident. **C**, Frontal and **D**, lateral chest radiograph in a patient with empyema shows an opacity creating the obtuse angles with the chest wall characteristic of an extraparenchymal process (*arrowhead*). An air-fluid level is present (*line*) and shows a different length in the frontal (**C**) and lateral (**D**) projections, which suggests extraparenchymal localization of the process. **E**, Frontal and **F**, lateral chest radiograph in a patient with lung abscess creating a broncho-pleural fistula shows an opacity with an air-fluid level (*double arrowhead line*) of roughly the same length in frontal (**E**) and lateral (**F**) projections, representing a lung abscess. Another process with air-fluid levels that differ in length markedly between the frontal (**E**) and lateral (**F**) projections (*line*) represents empyema. (Courtesy Michael Gotway, MD.)

eFIGURE IMAGE GALLERY

eFigure 18-1 Scattered radiation and scatter reduction. **A**, When an object is radiographed, some photons (the primary x-ray beam) (*solid line*) pass unaffected through the patient. Scattered or secondary radiation (*dashed lines*) arises at various angles to the primary beam and may expose the recording medium, reducing image contrast and detail. **B**, Scatter can be reduced with a grid. An antiscatter grid placed between the object and the recording medium reduces exposure due to scattered radiation. A grid is made of thin layers of radiation absorber (e.g., lead). Scattered radiation traveling at an angle to the grid layers is absorbed, although some scattered radiation at shallow angles may pass through. The grid ratio is equal to the height of the radiation absorber strips divided by the distance between them. **C**, Scatter can be reduced with an air gap. When the distance between the object and the recording medium is increased, an air gap is created. With an air gap, scattered photons at sufficiently great angles miss the recording device.

eFigure 18-2 A, The geometry of a standard 6-foot chest radiograph. For beam energies in the recommended range (>120 kVp), a grid is necessary between the patient and the detector to diminish scattered radiation. **B**, A 10-foot air gap or “space barrier” can also be used. The air gap obviates the need for a grid. The 10-foot tube-to-detector distance helps to minimize geometric enlargement. The avoidance of the grid diminishes patient radiation exposure.

eFigure 18-3 Portable chest radiograph shows malposition of an enteric tube. Frontal chest radiograph shows placement of an enteric tube in the right lower lobe bronchus. (Courtesy Michael Gotway, MD.)

eFigure 18-5 An intensive care unit portable radiograph demonstrates malposition of a right central venous catheter. The catheter has been inadvertently inserted into the right carotid artery; the tip (*arrow*) resides in the aortic arch. A large area of consolidation is seen in the left lung. (Courtesy Michael Gotway, MD.)

eFigure 18-4 A portable radiograph shows a misplaced central venous line. Note that the right external jugular venous catheter tip (*arrow*) is within the right internal jugular vein, rather than the superior vena cava. Extensive opacities (pulmonary edema) are present in both lungs. (Courtesy Michael Gotway, MD.)

eFigure 18-6 Portable intensive care unit radiography is useful in several situations. **A**, Chest radiograph performed following insertion of a left internal jugular central venous catheter shows the catheter (*arrows*) following a more medial and inferior course than expected for left internal jugular and brachiocephalic vein catheter placement. Sequential axial contrast-enhanced chest CT images near the thoracic apex (**B**), at the thoracic aortic arch (**C**), at the level of the left pulmonary artery (**D**), and at the level of the main pulmonary artery (**E**) shows the catheter (*arrow*) extending through the inferior margin of the left brachiocephalic vein (*arrowhead*, **B** and **C**) into an extravascular location more inferiorly, with surrounding active contrast extravasation (*) and hematoma resulting from venous perforation and pulmonary artery laceration. (Courtesy Michael Gotway, MD.)

eFigure 18-7 Sequelae of a malpositioned pulmonary artery (PA) catheter. The catheter (arrow = tip) extends too far peripherally into the segmental vessels of the right upper lobe artery. The catheter had been in this location for a number of hours. Note the opacity in the right upper lobe (arrowheads), representing pulmonary hemorrhage or infarction secondary to vessel obstruction by the PA catheter. (Courtesy Michael Gotway, MD.)

eFigure 18-8 Portable radiography has limitations. **A**, This anteroposterior (AP) supine portable radiograph was made in the intensive care unit. The energy of the beam was 100 kVp, and the focal spot–film distance was 40 inches. The pulmonary markings are poorly visualized because of a long exposure with motion blurring and a short focal spot–film distance with magnification and detail degradation. **B**, This radiograph was obtained from the same patient shortly after that shown in **A**, but in the main radiology department. The patient was sitting in a chair. The energy of the beam was 130 kVp, with a focal spot–film distance of 60 inches. Radiograph in **B** shows much better detail than radiograph **A** and also has less magnification. (Courtesy Michael Gotway, MD.)

eFigure 18-9 This block diagram shows components of a digital radiographic system. Image manipulation, subtraction, and other such functions are performed during the digital phase. (From Nudelman S: In Digital radiology—physical and clinical aspects: proceedings of meeting held at Middlesex Hospital and Medical School, London, England, March 9, 1983. London, 1984, Institute of Physical Sciences in Medicine, pp 1–43.)

eFigure 18-11 Unilateral hyperlucent lung due to patient rotation. Frontal chest radiograph rotated to a right anterior oblique position shows diffuse lucency affecting the left thorax. Focal lucency can result from air trapping due to obstructive lung disease or endobronchial obstruction, or, rarely, vascular obstruction (see eFigs. 54-15, 57-7, 57-9), or chest wall disorders (such as mastectomy or Poland syndrome), but is most commonly the result of technical factors. (Courtesy Michael Gotway, MD.)

eFigure 18-10 This digital (computed radiographic) study of the chest was made in an intensive care unit. **A**, This view resembles a “conventional” film-screen radiograph. **B**, This view was processed for edge enhancement. (Courtesy Michael Gotway, MD.)

eFigure 18-12 Lordotic chest radiography. **A**, Frontal chest radiograph shows how the anterior and posterior cranial ribs overlap with the clavicles, creating superimposition that often obscures abnormalities in the apices. **B**, Lordotic chest radiograph shows that the clavicles are now projected cranial to the first ribs, and the anterior and posterior portions of the ribs nearly overlap with one another, improving visualization of the pulmonary parenchyma in the lung apices. (Courtesy Michael Gotway, MD.)

eFigure 18-13 Value of oblique chest radiography. **A**, Frontal posteroanterior radiograph shows a possible nodular opacity (*arrow*) at the right apex, obscured by overlap of the right clavicle and anterior first rib. **B**, 5-degree right anterior oblique chest radiograph shows that the possible opacity “moves” relative to the clavicle and first rib, indicating that the lesion is unrelated to the anterior chest wall and resides within the lung. (Courtesy Michael Gotway, MD.)

eFigure 18-21 Ultrasound of pleural effusion. Ultrasound examination of the lower left chest shows effusion (**E**) cranial to the right hemidiaphragm (**arrows**). **Liv**, liver. (Courtesy Michael Gotway, MD.)

eFigure 18-22 Isotropic multiplanar imaging with multislice CT of the thorax. A–C, Axial (A), sagittal (B), and coronal (C) soft tissue images from a pulmonary CTA study show that the resolution and diagnostic quality of the sagittal (B) and coronal (C) imaging is identical to that of the source axial images (A). D, Axial and E, coronal images displayed in lung windows also show equivalent diagnostic quality. (Courtesy Michael Gotway, MD.)

Dose Report					
Series	Type	Scan Range (mm)	CTDIvol (mGy)	DLP (mGy-cm)	Phantom cm
1	Scout	-	-	-	-
200	Axial	I73.250-I73.250	1.52	0.76	Body 32
201	Axial	I62.250-I62.250	4.55	2.28	Body 32
2	Helical	I28.000-I175.500	7.17	138.97	Body 32
Total Exam DLP:				142.00	
1/1					

eFigure 18-23 CT “dose report.” The total radiation exposure associated with this CT examination is shown as both the CT dose index (CTDI_{vol}) and the dose-length product (DLP). Such dose reports are often recorded as DICOM images and archived as part of the CT examination in the radiology database, typically a PACS (Picture Archiving and Communication System). (Courtesy Michael Gotway, MD.)

Figure 18-24 Chest wall lesion simulating a solitary pulmonary nodule at chest radiography: value of chest CT. **A**, Frontal chest radiograph shows a right lower lobe opacity (*arrow*) simulating a pulmonary nodule. **B**, Axial chest CT displayed in lung windows shows a sclerotic lesion (*arrow*) within an anterior rib, which accounts for the chest radiographic abnormality; no lung nodule is present. (Courtesy Michael Gotway, MD.)

eFigure 18-25 CT features of malignant pulmonary nodules. **A**, Air bronchogram (*arrowhead*) within a solitary pulmonary nodule; **B**, vascular convergence sign—note pulmonary vessels (*arrowheads*) appearing to “converge” on the poorly defined pulmonary nodule; **C**, “notch” sign—note the lucent defect within the anterior portion of the lingular nodule (*arrowhead*), and; **D**, spiculation. Note that this nodule also shows a notch or small air bronchogram anteriorly. All four nodules show a pleural “tail”—linear opacities extending from the nodule to the visceral pleural surface. Once thought to be a feature suggesting a malignant etiology for a solitary pulmonary nodule, the pleural “tail” is actually a nonspecific finding. (Courtesy Michael Gotway, MD.)

eFigure 18-26 Failure of detection of calcification within a solitary pulmonary nodule at chest radiography: value of chest CT. **A**, Frontal chest radiograph shows a solitary pulmonary nodule (*arrow*) in the right lung. The nodule may be calcified, but the absolute determination of calcification within a nodule at chest radiography can be both difficult and occasionally inaccurate. **B**, Unenhanced chest CT displayed in soft tissue windows shows that the nodule (*arrow*) is almost entirely calcified. (Courtesy Michael Gotway, MD.)

eFigure 18-27 **A**, Frontal and **B**, lateral chest radiograph in a patient with a right middle lobe solitary nodule (*arrow*) does not clearly show calcification within the nodule. **C**, Axial chest CT displayed in lung windows shows a small focus of calcification (*arrowhead*) within the center of the nodule. This lesion was growing slowly and was resected; it proved to be a necrotic granuloma. (Courtesy Michael Gotway, MD.)

eFigure 18-28 Calcification in a bronchogenic carcinoma. **A**, Detail frontal chest radiograph shows a right upper lobe nodule (*arrow*), but calcification is not clearly seen within the lesion. **B**, Unenhanced chest CT displayed in soft tissue windows shows calcification (*arrowhead*) within the nodule. Note the heterogeneous appearance of this nodule; biopsy subsequently confirmed adenocarcinoma. (Courtesy Michael Gotway, MD.)

eFigure 18-29 Detection of fat within a nodule at chest CT: lipoid pneumonia. **A**, Axial chest CT displayed in lung windows shows a spiculated left lower lobe opacity associated with surrounding inhomogeneous lung opacity. The appearance resembles bronchogenic carcinoma. **B**, Axial chest CT displayed in soft tissue windows shows that the nodule contains low attenuation material consistent with fat (*arrowheads*), consistent with lipoid pneumonia. The patient was subsequently discovered to be using mineral oil as a laxative. (Courtesy Michael Gotway, MD.)

eFigure 18-30 Chest CT solitary nodule enhancement study: negative results. Axial chest CT imaging **A**, before intravenous contrast injection, **B**, at 1 minute, **C**, at 2 minutes, **D**, at 3 minutes and, **E**, at 4 minutes following intravenous contrast injection shows an unenhanced nodule (*arrow*) attenuation coefficient of 18 HU, and following intravenous contrast injection of 20 HU, 24 HU, 21 HU, and 23 HU at 1, 2, 3, and 4 minutes following intravenous contrast injection, respectively. The lack of significant intravenous contrast enhancement (i.e., >15 HU) at any of the 4 time points following intravenous contrast injection strongly suggests that the nodule is benign. (Courtesy Michael Gotway, MD.)

eFigure 18-31 Chest CT for lung cancer staging: tracheal involvement. Enhanced chest CT displayed in soft tissue windows shows a large right lung mass invading the mediastinum and clearly extending into the trachea. (Courtesy Michael Gotway, MD.)

eFigure 18-32 CT and MRI for lung cancer staging: mediastinal invasion. **A** and **B**, Axial (**A**) and coronal (**B**) unenhanced chest CT displayed in soft tissue windows shows a medial right upper lobe bronchogenic carcinoma invading the mediastinum—note the obliteration of mediastinal fat planes by the tumor (*arrowheads*) and the tumor's close approach to the right brachiocephalic artery. **C–E**, Axial T2-weighted (**C**), unenhanced axial T1-weighted (**D**), and enhanced coronal T1-weighted (**E**) MR images show the intermediate-to-low signal intensity tumor (*arrows*) extending into the mediastinal fat (the hyperintense, white stripe between the tumor and the trachea [T] in **C** and **E**). The tumor shows extensive contact with the mediastinum (margins of the tumor—mediastinal contact is indicated by *arrowheads*). The tumor also shows extensive contact with the right brachiocephalic artery (*double arrowheads*, **D**). (Courtesy Michael Gotway, MD.)

eFigure 18-33 Chest MRI for lung cancer staging: mediastinal vascular invasion. Enhanced, T1-weighted fat saturation MRI image shows a heterogeneously enhancing left lung mass clearly invading the left pulmonary artery (*arrows*). (Courtesy Michael Gotway, MD.)

eFigure 18-34 CT for lung cancer staging: chest wall and vertebral body invasion. Unenhanced axial chest CT displayed in soft tissue windows shows an extensive right apical neoplasm invading the posterior chest wall and vertebral body. (Courtesy Michael Gotway, MD.)

eFigure 18-35 CT for lung cancer staging: pleural dissemination. A and B, Axial chest CT displayed in lung windows shows extensive pleural nodularity (*arrowheads*) representing pleural metastatic disease from bronchogenic malignancy. (Courtesy Michael Gotway, MD.)

Figure 18-36 CT for lung cancer staging: tracheal carinal invasion. **A,** Axial contrast-enhanced chest CT shows extensive tumor involvement of the mediastinum with invasion of the tracheal carina. **B,** Axial contrast-enhanced chest CT in another patient shows tumor surrounding both mainstem bronchi at the level of the inferior margin of the carina. (Courtesy Michael Gotway, MD.)

Figure 18-37 Chest CT for lung cancer staging: summary of the CT approach to possible mediastinal invasion by bronchogenic carcinoma. **A and B,** Axial chest CT displayed in soft tissue windows shows extensive mediastinal tumor contact (>3 cm) and clear tumor nodules invading mediastinal fat (*arrowhead*). **C,** Axial enhanced chest CT displayed in soft tissue windows shows a medial left upper lobe neoplasm exerting mass effect on the adjacent mediastinal fat and obliterating the fat plane (*arrowhead*) normally surrounding the esophagus (*arrow*); endoscopic ultrasound confirmed invasion of the esophagus. **D,** Axial enhanced, T1-weighted MRI shows invasion of the hyperintense mediastinal fat (note the signal characteristics of normal mediastinal fat surrounding the left subclavian artery [LSCA] and left brachiocephalic vein [LBV]). The tumor invades the right brachiocephalic artery (*arrowhead*)—note the mass effect deforming this vessel and the small intraluminal soft tissue focus, representing tumor thrombus. **E,** Axial enhanced chest CT displayed in soft tissue windows shows a medial left lower lobe bronchogenic neoplasm contacting the mediastinum and descending thoracic aorta; the tumor contacts less than 90 degrees of the descending thoracic aortic circumference, which generally predicts the *absence* of vascular invasion. **F and G,** Axial enhanced chest CT displayed in soft tissue windows shows a medial left lower lobe bronchogenic neoplasm contacting the mediastinum and descending thoracic aorta; this tumor contacts greater than 90 degrees but less than 180 degrees of the descending thoracic aortic circumference, which is indeterminate as regards vascular invasion. **H and I,** Axial enhanced chest CT displayed in soft tissue windows shows a medial left upper lobe bronchogenic neoplasm contacting the mediastinum and left subclavian artery (*arrowhead*); this tumor contacts greater than 180 degrees of this vessel, suggesting the presence of vascular invasion. (Courtesy Michael Gotway, MD.)

eFigure 18-38 Chest CT aortography. Chest CT aortogram in a patient with Stanford type A aortic dissection shows an intimal flap (*arrows*) in the ascending and descending thoracic aorta. Note dilation of the ascending aorta. (Courtesy Michael Gotway, MD.)

eFigure 18-40 This patient had symptoms classic for aortic dissection. “White blood” cine MR images show an intimal flap within the aortic arch (*arrowheads*), consistent with aortic dissection. (Courtesy Michael Gotway, MD.)

eFigure 18-39 Value of retrospectively gated chest CT aortography for the evaluation of the aorta. Axial CT aortography image obtained with retrospective electrocardiographic gating (image reconstructed during diastole) shows a motion-free image. Note clarity of the aortic valve cusps. Compare with the nongated CT aortography image in [eFig. 18-38](#). (Courtesy Michael Gotway, MD.)

eFigure 18-41 Chronic pseudoaneurysm in a long-term survivor with undiagnosed traumatic aortic injury 17 years earlier. **A**, Chest CT aortogram at the level of the aortic arch reveals a pseudoaneurysm (*arrowheads*); note calcification along the medial wall of the lesion. **B**, Oblique sagittal three-dimensional MRA image shows the pseudoaneurysm (*arrowheads*) to advantage. (Courtesy Michael Gotway, MD.)

eFigure 18-42 Value of MRI in the assessment of congenital cardiovascular diseases: aortic coarctation. **A**, Oblique sagittal T1-weighted spin-echo image of the thoracic aorta shows focal, severe narrowing of the proximal descending thoracic aorta (*arrow*) consistent with aortic coarctation. **B**, Oblique sagittal volume-rendered image shows coarctation (*arrow*), as well as collateral vessel formation. The latter derive from intercostal (*single arrowheads*), internal mammary (*double arrowheads*), and chest wall arteries and indicate the presence of a significant pressure gradient across the coarctation. (Courtesy Michael Gotway, MD.)

Indications and Contraindications

INTRODUCTION

Image-guided *transthoracic needle biopsy* (TNB), which is typically performed using *computed tomographic* (CT) guidance under local anesthesia and conscious sedation, is a minimally invasive procedure that can provide a definitive cytologic, histologic, or microbiologic diagnosis in 90% of patients with localized thoracic lesions.¹ The decision to perform TNB in lieu of alternative invasive diagnostic procedures or imaging follow-up, particularly for indeterminate lung lesions, is usually made following a multidisciplinary review of relevant clinical, laboratory, imaging, and pathologic material and requires consideration of local expertise, the availability of alternative invasive diagnostic procedures, including bronchoscopy and *video-assisted thoracic surgery* (VATS), and the needs of the referring physician and patient.

Interventional radiologists also play an important role in the management of intrathoracic air and fluid collections, using cross-sectional imaging to guide catheter placement and monitor response to drainage, and in control of massive hemoptysis by embolization of bronchial or systemic arteries. More recently, CT-guided thermal ablation of early-stage lung cancer and limited pulmonary metastatic disease has shown efficacy as a minimally invasive alternative to surgical management and external beam radiation therapy in select patients with stage IA lung cancer or those with limited pulmonary metastases.

TRANSTHORACIC NEEDLE BIOPSY

INDICATIONS AND CONTRAINDICATIONS

The most common indication for TNB is the diagnosis of a solitary pulmonary nodule (Fig. 19-1).² Additional indications include diagnosis of a mediastinal mass, enlarged

hilar or mediastinal lymph node,³ chest wall mass, or pleural mass or thickening.⁴ Most often the primary diagnostic concern is malignancy, but the diagnosis of opportunistic lung infection producing focal lung lesions in immunocompromised patients is an additional indication for image-guided TNB. In these latter patients, the retrieval of material for microbiologic stains and cultures rather than cytologic analysis for malignancy is the primary purpose for TNB.⁵ In selected patients with known *non-small cell lung cancer* (NSCLC) based on cytologic analysis from prior biopsy, core tissue TNB can be performed for immunohistochemical analysis (e.g., breast cancer metastases assessed for the presence of estrogen and progesterone receptors)⁶ or molecular testing (e.g., epidermal growth factor receptor or *echinoderm microtubule-associated protein-like 4-anaplastic lymphoma kinase* [EML4-ALK] rearrangement quantification)⁷ to help guide therapy. Occasionally a lesion thought likely to be benign based on clinical and imaging analysis is sampled using TNB to provide a definitive benign diagnosis.

The only absolute contraindication to TNB is the inability of a patient to cooperate for safe and successful sampling of the thoracic lesion in question. Most adults, even those with compromised pulmonary function, can undergo successful image-guided TNB using local anesthesia and either conscious sedation or monitored anesthesia care. For sampling of small lesions (<15 mm in diameter), the patient must be able to hold his or her breath when instructed to allow the operator to position the needle accurately within the lesion for successful retrieval of cytologic material. For larger lesions, particularly those at the lung periphery and those in the upper lobes that are less subject to craniocaudal motion during normal breathing, breath-holding is less important and TNB can be safely performed in most such patients without the need for the patient to respond to verbal commands. TNB can be performed selectively in patients receiving general anesthesia and endotracheal

Figure 19-1 Transthoracic needle biopsy of a solitary pulmonary nodule. CT with patient prone during transthoracic needle biopsy showing the vertical course of the coaxial needle with its tip at the edge of a 1-cm left upper lobe nodule.

intubation when necessary. Even patients with severe dyspnea—who are unable to lie recumbent for CT-guided or fluoroscopically guided biopsy and cannot hold their breath—can undergo successful ultrasonographically guided TNB in the sitting position if the lesion to be sampled in the lung or pleura provides an adequate intercostal acoustic window to allow real-time visualization and biopsy. As with superior mediastinal lesions, an ultrasonographically guided suprasternal approach with the patient in the sitting position can be used.

Bleeding diatheses are only a relative contraindication to TNB and if identified can usually be corrected before the procedure. Although no objective data exist showing an increased risk for bleeding from TNB in patients with abnormal clotting parameters, such as elevated international normalized ratio higher than 1.5 or a platelet count lower than 50,000 cells/ μ L, most operators and published guidelines recommend preprocedure correction of abnormal bleeding parameters.⁸ Patients receiving antiplatelet agents, including aspirin and/or clopidogrel (Plavix) for prophylaxis after myocardial infarction, stroke, or recent coronary artery stent placement, who require TNB should have an assessment of the relative risks and benefits of discontinuing these agents compared with the potential bleeding complications induced by TNB. Published guidelines recommend discontinuing antiplatelet agents at least 5 days before TNB.⁸ Those patients who are considered to be at risk for thrombosis if anticoagulation or antiplatelet agents are withdrawn before biopsy can be bridged to receive intravenous heparin, which can be discontinued several hours before TNB, thereby providing a brief periprocedural window without anticoagulation. For large mediastinal masses or large peripheral lung or pleural/chest wall lesions, aspiration biopsy can be safely performed while the patient remains on anticoagulation or antiplatelet agents. If core tissue biopsy is required, typically for the diagnosis of an anterior mediastinal mass such as lymphoma or thymic neoplasm or for molecular analysis of NSCLC (adenocarci-

nomas), antiplatelet agents should ideally be discontinued for 7 days before biopsy. Patients who have had a prior pneumonectomy are at greater risk for respiratory compromise should they develop bleeding or pneumothorax from lung biopsy. However, because these complications can usually be anticipated and managed successfully, prior pneumonectomy does not preclude TNB for evaluation of a suspicious lesion in the residual lung.

PATIENT-LESION SELECTION AND PREPROCEDURE CLINICAL AND IMAGING EVALUATION

The decision to perform a TNB for diagnosis follows a thorough imaging evaluation and clinical assessment of the patient; typically this includes a consultation with a pulmonologist or oncologist who interviews and examines the patient to determine the clinical likelihood of malignancy after a suspicious thoracic lesion has been identified. For patients younger than 35 years without significant risk factors for malignancy who have focal lung lesions, imaging follow-up is almost invariably employed because the likelihood of malignancy in such patients is very low. Conversely, for patients with localized lesions who have a high prebiopsy likelihood of lung cancer, direct referral for surgical consultation is reasonable and more cost-effective, because the result of TNB will be unlikely to obviate resection of the lesion. Nevertheless, biopsy of likely malignant nodules can be of utility in patients who are poor surgical candidates, in whom the lesion is not amenable to VATS resection for intraoperative frozen section diagnosis, and in those with a history of prior malignancy in whom metastatic disease is a consideration and a TNB diagnosis of metastatic disease would not lead to surgical metastasectomy. For anterior mediastinal masses, core biopsy is almost always necessary for the initial diagnosis of lymphoma, particularly if diagnosis would preclude unnecessary sternotomy and resection, because these lesions are treated with radiation therapy and/or systemic chemotherapy.

It is important to determine the following before the procedure: (1) if TNB will alter the therapeutic approach to the lesion in question and (2) if a patient with suspected malignancy would opt for treatment based upon the results of the procedure should it yield malignant material. It is reasonable to refer patients with a high likelihood of NSCLC directly to VATS with sublobar or wedge resection for initial diagnosis because this procedure may provide both diagnostic material and definitive treatment, particularly for smaller, peripheral lung lesions likely to reflect adenocarcinoma as determined by thin-section CT analysis. In patients with stage I NSCLC who are older than 75 years, segmentectomy or extended wedge resection may be offered as an effective and potentially beneficial alternative to lobectomy, particularly if the patients have indolent (i.e., ground-glass or subsolid) lesions or significant medical comorbidities such as severe chronic obstructive pulmonary disease.⁹

All patients referred for image-guided TNB should have a recent (optimally within 4 weeks of the procedure) thin-section (<2 mm slice thickness) CT examination of the lesion to be sampled. For TNB of mediastinal masses, enlarged mediastinal nodes, or pleural and chest wall masses, a recent contrast-enhanced CT or magnetic

resonance imaging study helps determine the vascularity of the lesion and its proximity to critical vascular structures.

Informed consent is obtained on arrival to the radiology department for all patients undergoing TNB by either the individual performing the procedure or a health care professional who is able to describe the procedure accurately and answer questions for the patient and accompanying family members. The informed consent should include a detailed explanation of the TNB procedure itself, the expected length of time in the department (typically 1 hour for the procedure and 3 hours of postprocedure observation), and the benefits of the image-guided transthoracic approach compared with alternative noninvasive diagnostic options, including the option of not undergoing any further diagnostic procedures, once the risks and benefits of TNB have been described. The published incidence of TNB-induced pneumothorax (approximately 20%), chest tube insertion (3%), and hemoptysis (5%)¹⁰ are provided before the patient signs the printed consent form.

CHOICE OF IMAGING GUIDANCE

Although TNB can be performed under fluoroscopic, CT, or ultrasonographic guidance, most operators use CT guidance exclusively or for the majority of their procedures. CT provides rapid and precise information regarding lesion and needle location. It is the only imaging modality that allows access to small, central lesions and safe access to enlarged mediastinal nodes (Fig. 19-2). The ability to visualize intervening structures allows the operator to avoid bullae or large vessels in the projected needle path. Precise needle tip localization allows for a more confident assessment of adequacy of needle placement, particularly within small lesions or those with a necrotic or cavitory center. Complications such as bleeding or pneumothorax are readily identified and expeditiously managed.

Fluoroscopy can be used for biopsy of lesions that are easily seen radiographically.¹¹ Ideally a biplane or C-arm unit that allows orthogonal views to be obtained during

needle placement without rolling the patient from the recumbent position helps assess the accuracy of needle placement into the lesion. Radiation dose to the patient from fluoroscopically guided TNB is generally lower than from CT-guided TNB. Because most radiologists currently performing TNB have been trained to use CT for abdominal and pelvic image guided interventions, most radiologists use CT to perform TNB.

Ultrasonography can be used to guide TNB in select cases.¹² Its primary advantage is real-time visualization during administration of local anesthesia, needle placement into the lesion, and lesion sampling, particularly automated core needle biopsy for histologic analysis. Intervening vascular structures are easily identified using Doppler so that they may be avoided. Although the technique is operator dependent, most radiologists have experience with diagnostic ultrasound probes and biopsy techniques that are easily applied to TNB. The use of ultrasonography to guide TNB is limited to lesions with an adequate acoustic window, such as anterior mediastinal masses and peripheral lung lesions with a broad pleural contact between the lesion and the chest wall (Fig. 19-3).

PROCEDURE

For CT-guided TNB the patient is placed recumbent and positioned to provide the shortest distance from the anticipated skin puncture site to the lesion, typically with the skin puncture site nondependent, allowing a vertical needle trajectory (see Fig. 19-1). For those patients unable to lie prone for the procedure because of breathing difficulties, the patient can be placed in the lateral decubitus position and a posterior puncture performed with the needle horizontally oriented. Most patients receive conscious sedation with relatively short-acting and readily reversible analgesic and amnestic agents, such as fentanyl and midazolam (Versed), respectively; if necessary, though, occasional patients require monitored anesthesia care or general anesthesia. For TNB performed using conscious sedation, a dedicated interventional radiology nurse administers the medications and

Figure 19-2 Transthoracic needle biopsy of mediastinal lymphadenopathy. **A**, Contrast-enhanced CT just below the level of the aortic arch shows an enlarged right lower paratracheal (4R) node (arrow). The patient had a left upper lobe mass (not shown). **B**, CT with the patient in the right lateral decubitus position showing the coaxial needle tip (arrowhead) within the enlarged right lower paratracheal node. Note the presence of an iatrogenic pneumothorax (asterisk) induced by a second blunt-tipped needle (arrow) that was initially placed into the pleural space with air injected to provide an extravascular pleural access to the node. Aspiration and core biopsy of the nodes confirmed the presence of contralateral (N3) nodal metastases from primary adenocarcinoma of the left upper lobe.

Figure 19-3 Ultrasonographically guided biopsy of large lung mass. **A**, Contrast-enhanced CT at the level of the right pulmonary artery showing a large right chest mass that has a broad area of contact with the pleural surface anteriorly and laterally. **B**, Transverse ultrasonographic image through the right anterior chest during core biopsy shows the mass (arrowheads) with an irregular echogenic region centrally. The biopsy needle is seen with its tip (arrow) within the mass. Histologic diagnosis was rhabdomyosarcoma.

monitors the patient's oxygen saturation, heart rate, respiratory rate, and level of responsiveness throughout the procedure. Ideally the patient should be able to cooperate with consistent breath-holding, which is necessary to position the biopsy needle accurately into small lesions for successful sampling; this is particularly important for lesions near the diaphragm, which show significant craniocaudal movement during even tidal breathing.

Once the patient has been properly positioned, a scout view (a planar image of the thorax analogous to a frontal radiograph that is used to plan for the axial scans) is obtained at functional residual capacity. All scans obtained through the region of interest are likewise obtained at normal end-expiration, which is a comfortable and reproducible lung volume for the patient to achieve, even when sedated. For TNB of small lung nodules, a reconstructed scan thickness of no greater than half of the diameter of the lesion should be obtained for identifying and marking the needle puncture site. This provides a detailed view of the ribs and intercostal space, helps visualize the anticipated needle path and any intervening large vessels or bullae to be avoided, and minimizes partial volume averaging when assessing the position of the needle tip relative to the lesion being sampled. Thin sections are particularly important when sampling lesions with subsolid attenuation, because it is important to identify any solid components within the lesion to target for TNB to provide a more confident cytologic diagnosis of malignancy. Once the thin sections encompassing the lesion have been obtained, an electronic grid is superimposed on the image at the desired level for needle entry at the technologist's console. This grid has major axes that mark the central meridian of the gantry in the coronal (x-axis) and sagittal (y-axis) planes and accurately correspond to laser lights on the CT gantry that project onto the patient's skin at the chosen axial level. Measurements are then made on the console from the axis closest to the desired entry point, and using a ruler on the patient's skin, this point is marked on the skin with an indelible marker.

The area is then prepared and draped with a sterilizing solution such as povidone-iodine (Betadine) or, for those with iodine allergies, chlorhexidine gluconate (Hibiclens). Local 2% lidocaine is administered subcutaneously to the

entry site and deeper, approaching the pleural surface, because the parietal pleura is heavily innervated and is best anesthetized before transpleural placement of the biopsy needle. We and most operators employ a coaxial needle approach, with an outer thin-walled guide needle 18- or 19-gauge in diameter placed through the chest wall and neighboring pleura and positioned with its tip at the edge of the lesion. Samples are obtained by placing a thin 20- to 22-gauge aspiration or core needle through the outer coaxial guide needle. Patient breath-holding during needle placement and repositioning at the same end-expiratory volume as directed for the preliminary scans is key to accurate needle placement. Rapid assessment of needle position following advancement and repositioning can be obtained by repeated axial images through the region or by using CT fluoroscopy, which allows the operator to obtain several quick contiguous low-dose thin-section images through the lesion and needle without having to leave the room.

Once the guide needle is properly positioned at the edge of the lesion to be sampled, aspiration biopsy is performed by using a rapid, rotatory, and to-and-fro motion with the inner needle attached to a syringe with suction applied. The needle-syringe combination is removed and handed to a cytotechnologist who expresses the contents onto a glass slide and then fixes the slide in alcohol. The slides are then stained using toluidine blue O and examined with a microscope kept in an adjoining area. Additional aspiration samples are typically obtained for immunocytochemical analysis, cell block, or stains and cultures when necessary. Core tissue biopsy specimens can be obtained using 20-gauge or larger automated cutting needles and are reserved for situations when histologic analysis is deemed necessary (Table 19-1).

Figure 19-4 Immunocytochemical diagnosis of primary pulmonary adenocarcinoma. **A**, Photomicrograph of aspirated specimen from a 71-year-old with a spiculated 15-mm upper lobe lung nodule showing cohesive clusters of large pleomorphic tumor cells with irregular nuclear contours and somewhat vacuolated cytoplasm (Papanicolaou stain; $\times 20$ original magnification). **B**, Thyroid transcription factor 1 immunocytochemical stain shows strong nuclear positivity, supporting pulmonary origin for this adenocarcinoma ($\times 20$ original magnification). (Courtesy Sharon Mount, MD, University of Vermont College of Medicine, Department of Pathology.)

It is our practice to have a cytopathologist attend each image-guided biopsy procedure performed in the radiology department to provide a rapid interpretation of aspirated material using light microscopy. This feedback helps guide the radiologist to obtain additional aspirated specimens for culture or immunocytochemical analysis or to perform core needle biopsy for histologic analysis.¹³ Ideally the pathologist responsible for processing and interpreting the specimens obtained from the biopsy procedure is consulted before the biopsy; this allows for review of existing pathologic specimens that help in the interpretation of the biopsy specimen. If a core biopsy for histologic material is anticipated, as for a mediastinal mass, or if cultures are likely to be obtained, the pathologist or cytotechnologist can bring the appropriate materials to the site of the biopsy in the radiology department to process the specimens. CytoLyt solution should be used to preserve cellular material for cell block, and Roswell Park Memorial Institute medium is used for flow cytometry when lymphoma is a diagnostic consideration and core needle biopsy is not possible. Culture medium should be used for processing aspirates for microbiologic stains and cultures, even when infection is remotely suspected.

The initial approach to the pathologic evaluation of a TNB specimen obtained from a lung nodule or mass is to determine whether the lesion represents a *small cell lung cancer* (SCLC) or an NSCLC. This distinction is typically made on the basis of light microscopic examination of the stained specimen.¹⁴ In the majority of biopsy specimens showing an epithelial malignancy, additional immunocytochemical tests performed on aspirated specimens are needed for definitive determination of the primary site of disease. Immunocytochemistry involves the binding of monoclonal or polyclonal antibodies to specific antigens within tumor cells that render these antigenic proteins visible under light microscopy.⁶ The technique is versatile, because it can be performed on cytologic material obtained fixed on slides, on a cell block, or on histologic specimens that are embedded in paraffin. By using positive and negative controls and assessing for nuclear, cytoplasmic, or membranous staining, the pathologist can incorporate the results of the immunocytochemical stains into the diagnostic algorithm

to render an impression regarding the specific cause of the sampled lesion.

Neuroendocrine markers, including chromogranin, synaptophysin, and CD56, are used to help confirm the diagnosis of small cell carcinoma, typical and atypical carcinoid tumors, and large cell neuroendocrine carcinoma. The markers most often used to determine the primary site of adenocarcinoma include thyroid transcription factor 1 (positive in lung and thyroid carcinoma) (Fig. 19-4), cytokeratin 7 and 20 (positive in lung and colorectal carcinoma, respectively, and helpful in distinguishing the two), CDX2 (positive in colorectal carcinoma) (Fig. 19-5), and estrogen receptors and HER2neu (positive in some breast carcinomas).¹⁵ Increasingly, core specimens for *EGFR* and *ALK* mutational analysis in patients with NSCLC thought to reflect adenocarcinoma should be obtained in patients who might benefit from such information (Fig. 19-6).

POSTPROCEDURE PATIENT MANAGEMENT

Once the biopsy has been completed, the patient is monitored and precautions are instituted to minimize delayed complications. Typically, patients are kept recumbent, ideally with the biopsy side down) in an effort to reduce the likelihood of air leak from the lung puncture site^{16,17} and to decrease the likelihood that any alveolar hemorrhage induced by the biopsy will be aspirated into the uninvolved lung and produce respiratory compromise. After the biopsy has been completed, the coaxial needle is withdrawn and the patient is immediately moved by radiology personnel from the biopsy table to a stretcher with the biopsy side placed dependently; this avoids straining that would produce an increase in intrathoracic pressure that would promote air leak. Some radiologists inject autologous blood clot or saline upon withdrawal of the outer guide needle of a coaxial system in an attempt to seal the visceral pleural surface to prevent an air leak and pneumothorax following the biopsy. The patient receives supplemental oxygen as a precaution while recovering from conscious sedation and also to help promote resorption of any pneumothorax.

An upright chest radiograph is obtained 2 to 3 hours following the completion of the biopsy to assess for

Figure 19-5 Immunocytochemical diagnosis of metastatic colorectal adenocarcinoma to lung. **A**, Photomicrograph of aspirated specimen from a patient with a history of stage III colorectal carcinoma and a solitary pulmonary nodule showing a cohesive cluster of tumor cells with rather uniform oval-shaped nuclei and delicate cytoplasm. (Papanicolaou stain; $\times 20$ original magnification). **B**, Immunocytochemical stain for CDX2 shows nuclear immunoreactivity, supporting the diagnosis of metastatic adenocarcinoma of gastrointestinal origin ($\times 20$ original magnification). Figure 19-6 Core biopsy for molecular analysis. CT performed at the level of the aortic arch shows the coaxial guide needle (arrow) with its tip at the anterior edge of a lobulated left upper lobe nodule, with the receptacle stylet of the inner cutting needle (between arrowheads) within the nodule. Core specimens were obtained for subsequent molecular analysis of this known pulmonary adenocarcinoma.

intraparenchymal or pleural hemorrhage and to exclude a pneumothorax. If no pneumothorax is detected, the patient can be safely discharged to home.¹⁸ If a small (< 2 cm from chest apex to pleural line of upper lobe) pneumothorax is present and the patient is asymptomatic, the patient can be discharged safely if the pneumothorax was detected on CT during the biopsy. Otherwise, the patient is observed for an additional 2 hours to confirm that the pneumothorax is stable; if it enlarges, a pleural drainage catheter is placed under fluoroscopic or CT guidance, and the patient is admitted for observation and management. Any symptomatic, moderate-sized (2 to 4 cm), large (> 4 cm), or enlarging pneumothorax is evacuated, and the patient is admitted for management. Select patients who undergo evacuation of a biopsy-induced pneumothorax with a catheter attached to a Heimlich valve can be safely managed on an outpatient basis, provided they have family or friends who can monitor them and if they live within short distance of a health care facility that can assess and manage them should their shortness of breath redevelop. Patients undergoing catheter

drainage have underwater seal and suction until the pneumothorax has resolved and no air leak can be demonstrated, at which time the catheter can be safely removed.

RESULTS

TNB has proven highly sensitive for the cytologic diagnosis of malignancy, with sensitivities exceeding 90% in the largest series published.^{1,2} The distinction between NSCLC and SCLC is made with high accuracy ($> 85\%$).¹⁴ A variety of factors have been shown to affect sensitivity, including the patient's ability to lie still and cooperate sufficiently, the presence of underlying emphysema, operator experience, lesion size and location, lesion density, and availability of expert cytopathologic analysis; all these factors affect the TNB success rate. Even for lesions smaller than 10 mm, the sensitivity rate of TNB is high.¹⁹ Certain lesions, particularly large mediastinal lymphomas, such as nodular sclerosing Hodgkin lymphoma, and certain forms of non-Hodgkin lymphoma that contain significant fibrosis, localized fibrous tumors of pleura, and neurogenic lesions can be more difficult to diagnose cytologically; core needle biopsies are typically obtained for definitive diagnosis of these lesions. TNB samples of subsolid adenocarcinomas can be difficult to distinguish cytologically from atypia or adenomatous hyperplasia, although our experience suggests that the yield of TNB from these lesions is similar to that for solid nodules.

Precise cytologic diagnosis of benign pulmonary lesions, such as granulomas, is more difficult than that of malignant lesions because their relatively small size and typically hypocellular, fibrotic matrix makes retrieval of diagnostic material from TNB difficult. Core needle biopsy as an adjunct to cytologic analysis alone can increase the diagnostic yield from TNB of benign lesions to approximately 80%.²⁰ Pulmonary hamartomas, particularly those with a significant cartilaginous component, can be difficult to aspirate, and core needle biopsy may be necessary for these lesions. Nevertheless, a skilled cytopathologist can make the diagnosis of a pulmonary hamartoma if provided adequate cytologic material (Fig. 19-7).

The diagnostic yield of TNB for infection is somewhat lower than for malignancy. However, TNB can identify the

causative microorganisms producing focal lesions in 80% of immunocompromised patients with suspected lung infection.²¹

COMPLICATIONS

The most common complications of TNB include pneumothorax and bleeding. Pneumothorax develops in approximately 20% of patients undergoing TNB, of whom 3% require catheter or tube drainage.¹⁰ Factors that may be associated with an increased rate of TNB-induced pneumothorax include operator inexperience, advanced patient age, smaller lesion size, greater lesion depth from the pleural surface, the presence of underlying emphysema or obstructive lung disease, larger outer coaxial needle diameter, prolonged needle dwell time, and greater obliquity of the angle between the biopsy needle and the transgressed visceral pleural surface.²²⁻²⁴

Hemorrhage (eFig. 19-1) with or without hemoptysis develops in approximately 5% of patients undergoing TNB but is rarely the cause of prolonged observation, hospitalization, or need for transfusion. Biopsy-induced hemorrhage can preclude successful completion of TNB if it leads to intractable coughing or if blood at the biopsy site in the lung obscures the lesion being sampled, thereby rendering further attempts at accurate sampling impossible.

Rare complications of TNB include hemothorax from intercostal artery damage (see eFig. 19-1), air embolism (eFig. 19-2), malignant seeding of the biopsy path, and, rarely, death.

CATHETER DRAINAGE OF INTRATHORACIC COLLECTIONS

Image-guided catheter or tube drainage of intrathoracic collections is an effective, minimally invasive method for treating a spectrum of intrapleural and intrapulmonary collections (see additional discussion in Chapter 79). This section will review the common indications, imaging considerations, catheter placement, and postprocedure man-

agement of intrathoracic collections with a review of complications and results in selected patients.

PARAPNEUMONIC EFFUSIONS—EMPYEMA

Intrapleural collections amenable to image-guided drainage include a wide spectrum of common causes of pleural effusions (see additional discussion in Chapter 80). Selected patients with complicated parapneumonic effusions, defined as those unlikely to resolve spontaneously with treatment of the underlying pulmonary infection, or frank empyema can benefit from image-guided drainage, thereby avoiding prolonged hospitalization and open surgical drainage and/or decortication procedures (Table 19-2).

According to the American College of Chest Physicians consensus statement on the medical and surgical management of parapneumonic effusions, the anatomy of infected pleural fluid collections, the presence or absence of bacteria within the parapneumonic effusion, and pleural fluid chemistry have prognostic utility for predicting patient morbidity and mortality.²⁵ Ultrasonography can detect very small parapneumonic effusions and helps guide safe, diagnostic sampling of these collections when necessary. Ultrasonographic findings that predict the likelihood of successful catheter or tube drainage, corresponding to early exudative stage parapneumonic collections, include small- to moderate-sized free-flowing, nonloculated collections lacking internal echoes or septations. Alternatively, ultrasonographically detected septations within complicated parapneumonic collections and empyemas make it more likely that a longer duration of chest tube drainage and longer hospital stay will be necessary.

Because these collections are likely to require fibrinolytics (see subsequent discussion) and ultimately surgical intervention, primary surgical treatment may be warranted in this subgroup of patients.²⁶ Analysis of the entire extent of the pleural fluid collection and characterization of underlying lung and adjacent chest wall disease is best demonstrated on contrast-enhanced multidetector CT, which provides axial, sagittal, and coronal reformatted images that offer important information when considering therapeutic options for parapneumonic effusions. Similarly, early-stage exudative or fibrinopurulent effusions characterized on CT as dependent meniscoid or unilocular collections are best suited to small-bore image-guided catheter placement, with case series reporting success rates as high as 93%.²⁷ The presence of enhancing visceral and parietal pleural layers encompassing a loculated pleural fluid collection is relatively specific for the presence of an empyema, although the identification of this split pleura sign does not preclude successful catheter drainage. Selected patients with unilocular empyemas or multiloculated collections who are poor surgical candidates for open management of infected pleural collections can be successfully managed with one or more image-guided catheters, either as definitive therapy or as a bridge to definitive surgical treatment.

After ultrasonographic localization for small-bore image-guided catheter treatment of parapneumonic effusions, we prefer a trocar catheter placement technique using a 14- or 16-French drainage catheter) for free-flowing or unilocular, nonseptated parapneumonic collections that have an adequate area of contact with the costal pleural surface and sufficient width to allow safe placement of the sharp-tipped trocar-catheter combination into the dependent part of the collection (Fig. 19-8). For treatment of frank empyemas or large collections with ultrasonographically or CT-detected septations in nonsurgical patients, we prefer a large 28-French tube placed using a Seldinger technique, which involves placement of an 18-gauge needle followed by a guidewire and sequential dilation to 30-French diameter before tube insertion. If necessary, multiple catheters or tubes can be employed to drain different locules within the

chest as depicted on CT, particularly for those patients felt to be poor candidates for primary surgical drainage.²⁷

Once catheters and tubes have been placed under imaging guidance, the patient's clinical status, tube output, and radiologic studies are reviewed daily to determine the effectiveness of drainage. The tube or catheter should be flushed with saline three times a day to maintain patency of the lumen and prevent occlusion of the drainage holes located in the distal aspect of the device by fibrin and debris. An inadequate response to treatment is defined as a lack of improvement in fever, peripheral white blood cell count, and oxygenation, with persistent dyspnea or pain; importantly, a persistent or enlarging collection on radiography or CT warrants a reevaluation of the patient with consideration of additional maneuvers to improve drainage or proceeding to surgical management. Assuming radiologic evaluation and management demonstrates adequate positioning and functioning of the drainage catheter or tube within the collection(s), inadequate drainage may require increasing the size of the tube and/or the use of intrapleural fibrinolytic agents to promote drainage. Contrast-enhanced chest CT evaluation is helpful for patients who have failed to improve following adequate tube placement to detect undrained locules and to guide tube exchange when necessary; CT can also assess the status of the underlying pneumonia or abscess to determine if lack of clinical improvement is more a result of progressive pulmonary infection than inadequate pleural drainage. Once there has been clinical and radiographic resolution of the collection and drainage has diminished to less than 100 mL/day, the catheter is removed.

The use of intrapleural fibrinolytic agents as an adjunct to catheter or tube drainage can aid in the successful management of complicated parapneumonic effusions and empyemas, particularly those collections in the fibrinopurulent or organizing stages of empyema formation.²⁸ Multiple case series assessing the use of intrapleural streptokinase, urokinase, or recombinant tissue plasminogen activator have shown radiographic resolution of infected pleural fluid collections (see Fig. 19-8), obviating the need

Figure 19-8 CT-guided catheter drainage of loculated empyema treated with intrapleural fibrinolytics. **A**, Contrast-enhanced CT displayed in mediastinal windows through the level of the left atrium showing a unilocular collection in the lower posterior left pleural space. Note subtle enhancement of the parietal pleural surface (arrowheads), suggesting presence of an exudative effusion. **B**, Repeat contrast-enhanced CT scan displayed in mediastinal windows performed through the lower lobes following placement of a 14-French pigtail drainage catheter and intrapleural instillation of recombinant tissue plasminogen activator for 5 days shows the catheter (arrow) in the posterior pleural space with evacuation of the pleural fluid.

for surgical drainage. Given problems with allergic reactions to streptokinase and the limited availability of urokinase, most centers, including ours, use recombinant tissue plasminogen activator for intrapleural fibrinolysis. Although there is literature to indicate that intrapleural fibrinolytics provide no added benefit compared with drainage alone in terms of survival, length of hospital stay, or need for open surgical drainage,²⁹ methodologic limitations of these studies have been identified.³⁰

Specifically, the largest randomized controlled trial, the MIST1 study, used only chest radiography to assess pleural fluid morphologic characteristics, which is not as accurate as CT or ultrasonography to assess for septations, loculations, and intrafissural and medial pleural locules.²⁹ In support of the use of intrapleural fibrinolytics in the adult population is a recent meta-analysis published in 2012 of seven randomized controlled studies, conducted primarily in Europe, comparing fibrinolytics with placebo using data collected through October 2011.³¹ This study showed that fibrinolytics are potentially beneficial for the management of parapneumonic effusions and empyemas in adults.

The most recent evidence supporting intrapleural therapy for the treatment of pleural infection is a randomized controlled trial comparing intrapleural recombinant tissue plasminogen activator in combination with DNase or with either agent alone versus no intrapleural treatment, which showed a significant change in mean pleural opacity on radiography 1 week after 3 days of twice-daily intrapleural administrations of both agents.³² Subgroup analysis showed no differences in treatment effect between use of large- or small-bore tubes, purulent or nonpurulent pleural fluid, or presence or absence of loculations. In addition, frequency of referral for surgery and length of hospital stay were reduced for patients receiving the combined intrapleural treatment compared with those receiving either agent or no agent alone, and there was no difference in adverse events among all groups. Although further study of intrapleural treatment for infected pleural collections is needed, this latter study suggests that the combination of recombinant tissue plasminogen activator for fibrinolysis and DNase to

cleave extracellular DNA and reduce pleural fluid viscosity may become the standard of treatment for selected patients with infected pleural fluid collections. However, the potential cost-effectiveness of intrapleural fibrinolytic treatment has not been well delineated.

MALIGNANT PLEURAL EFFUSIONS

A malignant pleural effusion is defined by the presence of positive cytologic results on pleural fluid analysis or positive pleural biopsy in a patient with malignancy. Malignant pleural effusion is most commonly due to lung or breast cancer, although in 10% to 15% of patients with malignant effusions, no primary tumor can be identified.³³ Catheter drainage of a malignant effusion, followed by either chemical pleurodesis or the use of an indwelling tunneled catheter, can be used to provide extended drainage of symptomatic malignant effusions in patients with a limited life expectancy and is a reasonable alternative to thorascopic or open surgical drainage and sclerosis (Fig. 19-9).³⁴

Because the majority of symptomatic and recurrent malignant effusions are large and free flowing, catheter placement for drainage and subsequent talc pleurodesis is typically performed using ultrasonographic guidance with the patient in the sitting position. A diagnostic ultrasonographic examination is performed to confirm the size and dependent location of the collection. A lower intercostal approach is used to place the catheter tip in a dependent location to facilitate drainage of dependent fluid no matter what position (i.e., supine or upright) the patient maintains. Optimally the catheter is placed through the junction of the serratus anterior and latissimus dorsi muscles along the lower posterolateral chest wall where it traverses the least amount of muscle and will not be compressed or kinked when the patient lies on his or her back. For serous or thin serosanguineous effusions a 10- or 12-French catheter allows for adequate drainage, whereas a larger diameter (12- or 14-French) is employed if talc slurry is to be administered for subsequent pleurodesis following adequate drainage of the pleural space and reexpansion of the

Figure 19-9 Ultrasonographic-guided drainage of a malignant pleural effusion. **A**, Frontal chest radiograph in a 68-year-old woman with a malignant right pleural effusion from metastatic ovarian carcinoma showing a right pleural effusion with passive right lower lobe atelectasis. **B**, Repeat radiograph after ultrasonographically guided placement of a 10-French pigtail catheter shows the catheter (arrow) in the dependent aspect of the right pleural space with evacuation of the effusion and reexpansion of the lower lobe.

underlying lung. Loculated collections can benefit from intrapleural fibrinolytics to lyse adhesions before attempts at chemical sclerosis.

If talc slurry is used for chemical pleurodesis, 4 g of talc mixed with 50 mL of normal saline is injected into the evacuated pleural space and left to dwell for 1 hour. Suction is then reinstituted, with the catheter removed once drainage has diminished to less than 150 mL/day and the patient has shown symptomatic and radiographic improvement. Complete response rates of 70% and higher have been reported for use of small-bore catheters and talc pleurodesis in selected patients.³⁵

PNEUMOTHORAX

Fluoroscopy- or CT-guided small-bore (<12-French) catheter drainage of pneumothorax can be employed for management of moderate-to-large or enlarging pneumothoraces, or any size pneumothorax that is symptomatic (see additional discussion in Chapter 81). Today, most often image-guided catheter drainage of pneumothorax is performed for pneumothorax that develops as a complication of TNB or thermal ablation of localized thoracic malignancy, although catheter drainage has been traditionally used to treat spontaneous pneumothorax and pneumothorax related to traumatic causes (Fig. 19-10).³⁶

For pneumothorax resulting from a CT-guided procedure, catheter placement is typically performed using CT. Otherwise, fluoroscopy provides real-time visualization of catheter placement and is the preferred guidance modality. An approach via the anterior 2nd intercostal space in the midclavicular line is typically used, although in women a lateral approach via the 5th to 6th intercostal space in the midaxillary line can be employed to avoid traversing breast tissue. Conscious sedation and local anesthesia are used, with adequate numbing of the heavily innervated parietal pleura with lidocaine being the key to patient comfort during catheter placement. We employ a trocar technique in which, following successful pleural anesthesia, a drain-

age catheter with a self-retaining pigtail tip configuration loaded onto a stiffening cannula and inner sharp-tipped trocar is placed into the pleural space and positioned into the pleural apex under direct visualization. Once the catheter tip is confirmed to lie within the apex of the pleural space, the pigtail tip is “locked” into position by use of a string that opposes the catheter tip to a more proximal portion of the catheter, and lidocaine is injected through the catheter lumen to provide local anesthesia to the apical pleura, which if contacted by the catheter can produce significant ipsilateral shoulder pain. Alternatively, the catheter can be introduced into the pleural space in a stepwise fashion, whereby a hollow needle is initially used to access the pleural space, followed by placement of a guidewire and then progressive dilation of the track to the diameter of the catheter to be placed for drainage.

Once the catheter has been successfully placed, it is affixed to the skin using an adhesive ostomy-type dressing with ties surrounding the catheter and is attached to a Pleur-evac device for suction drainage. The catheter should be flushed two to three times a day to prevent fibrin deposition that can occlude the drainage holes situated in the distal pigtail-shaped component of the catheter.

Success rates for small-bore catheter drainage of iatrogenic pneumothorax exceed 85% in multiple series,^{36,37} but drainage is also successful in the majority of patients when used in emergency settings for noniatrogenic traumatic and spontaneous pneumothoraces.³⁸

LUNG ABSCESS

Although postural drainage and antibiotics are the standard methods for medical management of lung abscess, those collections that do not readily communicate with an airway or for which medical management is unsuccessful can be treated with catheter drainage under CT guidance, as discussed in Chapter 33. Because most of these collections are pleural based, with intrapleural adhesions typical at the site of pleural contact, the risk for development of a

Figure 19-10 Catheter drainage of a biopsy-induced pneumothorax. **A**, Upright frontal chest radiograph obtained 2 hours after CT-guided biopsy of a cavitary metastasis to the right lung showing a large right pneumothorax. **B**, Spot radiograph during drainage catheter placement shows the catheter (arrow) placed via the second anterior intercostal space with the catheter coursing over the right pleural apex (asterisk). **C**, Repeat frontal radiograph obtained the following morning shows the catheter over the right lung apex and complete evacuation of the pneumothorax.

bronchopleural fistula is minimal. As with drainage of complex pleural collections, image-guided catheter drainage can be definitive or can be used as a bridge to surgical management.³⁹

Drainage of lung abscess or an infected bulla is best performed under CT guidance, because this provides direct visualization of the catheter course and helps minimize traversal of normal intervening lung by the drainage catheter. The principles of catheter placement are similar to those for drainage of abscesses elsewhere in the body. The patient is positioned to allow access to that part of the abscess that is closest to a pleural surface. If possible, it is best to avoid placing the patient in the decubitus position with the unaffected side dependent, because pus or blood can spill from the abscess cavity into the dependent lung during catheter placement, producing respiratory compromise. We typically use a trocar technique for catheter placement into larger abscesses, whereby the drainage catheter (typically 12- or 14-French) is loaded over both a stiffening cannula and a sharp-tipped trocar that allows puncture of the cavity wall. Alternatively, for smaller collections, a needle can be placed into the cavity, its position confirmed on repeat CT imaging or aspiration of pus through the needle, followed by placement of a guidewire into the cavity and progressive dilation until the desired catheter diameter is achieved. The catheter is then placed directly into the abscess cavity over the guidewire. The pigtail-shaped tip should be placed into the dependent part of the collection to facilitate dependent drainage of the infected fluid. Once properly positioned, the drainage catheter is affixed to the skin and attached to suction drainage until fluid drainage ceases and there is evidence of clinical and radiologic improvement (Fig. 19-11).

There are only limited case series describing the success rate and complications from percutaneous catheter drainage of lung abscess. A recent update summarizing the results of 21 studies showed a success rate of 84%, with a complication rate of 16%.⁴⁰ Clogging of smaller drainage tubes, pneumothorax, hemothorax, hemoptysis, and bron-

chopleural fistula formation are the most frequent complications following catheter abscess drainage.

BRONCHIAL ARTERIOGRAPHY

INDICATIONS AND CONTRAINDICATIONS

The most common indication for urgent or emergent bronchial arteriography is massive hemoptysis. The most commonly used criterion for massive hemoptysis is 500 mL of expectorated blood in a 24-hour period, although it has been defined variably from as low as expectoration of 100 mL to greater than 1000 mL of blood in a 24-hour period.⁴¹ The need for emergent intervention is most commonly determined by the patient's sudden onset of severe hypoxemia from intrapulmonary bleeding and retention of blood; hemoptysis rarely causes life-threatening exsanguination. For practical purposes, any amount of hemoptysis that causes life-threatening inability to maintain a patent airway should be considered emergent.

Massive hemoptysis most commonly results from chronic inflammatory lung diseases due to bronchiectasis, cystic fibrosis (Fig. 19-12), or complicating fungal infection.⁴¹ Neoplasm, such as bronchogenic carcinoma or vascular metastatic disease, can also cause hemoptysis. Less common causes of hemoptysis include lung abscess, pneumonia, chronic bronchitis, ruptured bronchial artery aneurysm, pulmonary arteriovenous malformations, and traumatic or inflammatory pulmonary artery aneurysms. In resource-poor countries, pulmonary tuberculosis is by far the most common cause of massive hemoptysis.

Indications for nonemergent bronchial arteriography and intervention include patients with non-life-threatening chronic hemoptysis that is unresponsive to medical therapy.⁴² Less frequent indications for bronchial arteriography include bronchial artery aneurysms or pseudoaneurysms and arteriovenous fistulas. A failure of a thoracic stent graft caused by bronchial arterial collateral flow into

Figure 19-11 CT-guided drainage of right lung abscess. **A**, Coronal-reformatted CT scan displayed in bone windows through the posterior thorax in a 19-year-old man showing a large cavitary lesion extending from the upper to the lower lobe, representing an abscess. There is a multiloculated right paraneumonic effusion (asterisks). **B**, Upright frontal chest radiograph following CT-guided placement of a 16-French curved drainage catheter (arrow) into the abscess and a 12-French pigtail catheter (arrowhead) into the lower lateral right pleural fluid collection shows improvement in the abscess and pleural collection. The patient showed significant clinical improvement following the drainage.

Figure 19-12 Left bronchial arteriogram in a patient with cystic fibrosis and massive hemoptysis. A selective left bronchial arteriogram demonstrates abnormally enlarged and tortuous left bronchial arteries. Bronchoscopy diagnosed acute hemorrhage from the apicoposterior segment of the left upper lobe.

the aneurysm sac (a type II endoleak) is an additional rare indication for bronchial arteriography and intervention. Bronchial arteriography and intervention has been used for patients with lung cancer and other intrathoracic malignancies that can produce significant bleeding, such as hypervascular metastases to the chest. Relative contraindications to bronchial arteriography include severe iodinated contrast allergy and acute or chronic renal disease. Severe aortoiliac or upper extremity occlusive disease may also pose a challenge in accessing the origins of the bronchial arteries.

Conservative management of massive hemoptysis is associated with a mortality rate of 50% to 100%.⁴³ Moreover, reported mortality rates for surgery performed for massive hemoptysis are as high as 35%. Bronchial artery embolization is a safe and effective alternative to medical or surgical management of hemoptysis with successful control of acute life-threatening hemoptysis in 73 to 98% of patients, although hemoptysis may recur.⁴²⁻⁴⁴

The bronchial arteries have variable anatomy with multiple different combinations of origins, branching patterns, and vessel course. The bronchial arteries most commonly originate from the descending thoracic aorta between the levels of the T5 and T6 vertebral bodies (eFig. 19-3) but can originate anywhere from T3 through T7 levels. Eighty percent of individuals will have a right bronchial artery that arises as a common *intercostobronchial trunk* (ICBT) from the posterolateral aspect of the thoracic aorta. The other bronchial arteries arise from the anterolateral aspect of the thoracic aorta. Four classic branching patterns have been described: two on the left and one on the right arising as an intercostobronchial trunk (40%); one on the left and one intercostobronchial trunk on the right (20%); two on the left and two on the right (20%); and one on the left and

two on the right (10%) (Fig. 19-13).^{41,43} Right and left bronchial arteries can originate from the thoracic aorta as a common trunk.

Anomalous bronchial arteries, which may be found in up to 35% of individuals, may arise from the aortic arch, intercostal arteries, internal mammary arteries, thyrocervical trunk, costocervical trunk, brachiocephalic artery, subclavian artery, or inferior phrenic artery. Anomalous bronchial vessels follow the course of the major bronchi. The arteries supplying the chest wall and diaphragm can also be recruited as systemic nonbronchial collaterals in the setting of pleural or parenchymal disease. These collaterals typically supply the lung after directly crossing diseased pleura (eFig. 19-4) or via the pulmonary ligament. Unlike the bronchial artery collaterals, these systemic collaterals do not follow the course of the bronchi. Assessing the presence of anomalous or collateral blood supply is important when evaluating hemoptysis, but, when the bronchial artery supply to a known parenchymal abnormality is not demonstrated during angiography of the conventional bronchial arterial branches, the procedure can become difficult and time consuming.

PULMONARY ARTERIOGRAPHY

INDICATIONS AND CONTRAINDICATIONS

Multidetector *CT pulmonary angiography* (CTPA) has largely replaced conventional pulmonary angiography in the localization and diagnosis of pulmonary arterial pathologic conditions, particularly for pulmonary embolism (see Chapter 57). Therefore diagnostic CTPA is rarely performed in modern practice for purely diagnostic purposes but is more commonly employed as a navigating tool before transcatheter pulmonary artery intervention. Nevertheless, the most common indications for conventional CTPA are acute pulmonary embolism and diagnosis of pulmonary arteriovenous malformations (Fig. 19-14) as discussed further in Chapter 61. Less common indications for pulmonary arteriography include chronic pulmonary embolism, pulmonary sequestration, pulmonary artery stenosis, pulmonary aneurysm or pseudoaneurysm, and pulmonary artery neoplasms.⁴⁵⁻⁴⁷ Relative contraindications for pulmonary arteriography include severe contrast allergy, severe pulmonary hypertension, and left bundle-branch block.

The main pulmonary artery is intrapericardial. It starts anteriorly at the pulmonic valve then runs in a posterior and cranial direction until it divides into the right and left main pulmonary arteries. The right main pulmonary artery crosses the mediastinum posterior to the ascending aorta and superior vena cava and anterior to the carina and right main bronchus. Leaving the right lung hilum and lateral to the mediastinum, the artery branches into upper and lower trunks and then into lobar and segmental arteries that generally parallel the bronchi. The left main pulmonary artery continues superiorly and then crosses anterior to the left main bronchus and just inferior to the aortic arch before coursing posteriorly to the left lung hilum. At the left lung hilum, the left main pulmonary artery provides segmental arterial branches to the upper lobe before continuing as a single trunk to supply the lower lobe. Blood supply to the

Figure 19-13 The four most common bronchial artery branching patterns (viewed from posterior). **A**, Two left vessels and one right vessel that represents an intercostobronchial trunk. **B**, One left vessel and one intercostobronchial trunk vessel on the right. **C**, Two left and two right (one intercostobronchial trunk and one bronchial artery) vessels. **D**, One left and two right (one intercostobronchial trunk and one bronchial artery) vessels. (Redrawn from Cauldwell EW, Siekert RG, Lininger RE, Anson BJ: The bronchial arteries: an anatomic study of 105 human cadavers. *Surg Gynecol Obstet* 86:395–412, 1948.)

Figure 19-14 Pulmonary arteriovenous malformation on pulmonary angiography. A selective right descending pulmonary arteriogram in a 64-year-old woman with hereditary hemorrhagic telangiectasia demonstrates a pulmonary arteriovenous malformation (arrow) in the middle lobe. Note characteristic feeding artery (A) and early draining vein (V).

lingula is variable but usually arises from the lingular branch of the left upper lobe. As with the right lung, the left pulmonary artery lower lobe trunk then branches into segmental vessels that follow the bronchi.

THERMAL ABLATION OF LOCALIZED LUNG CANCER AND PULMONARY METASTATIC DISEASE

INDICATIONS AND CONTRAINDICATIONS

Thermal ablation of lung nodules using *radiofrequency* (RF) waves, microwaves, or a cryoprobe has been used to obtain local control of malignancy in the chest for over 10 years.⁴⁸⁻⁵⁰ All three minimally invasive techniques involve image-guided targeting of lung nodules or masses using needles that induce tumor necrosis via either coagulation necrosis (RF ablation, microwave) or freezing and thawing of tissues (cryoablation). Although all three techniques have been used in the treatment of localized thoracic malignancy, the most extensive experience has been with RF ablation. When used in the chest, the needle probes are usually placed via CT guidance with the patient under conscious sedation as with TNB.

Table 19-3 Indications for Thermal Ablation of Lung Tumors

Stage IA (T1a or T1b) non-small cell lung cancer in nonsurgical candidate
Limited (<4) pulmonary metastases; all < 3 cm diameter; primary tumor controlled
Control of localized recurrence of lung cancer in patient with previous advanced-stage lung cancer
Selected patients with unresectable carcinoid tumor of lung

Two primary groups of patients are considered for thermal ablation of the lung: (1) those with small, stage IA (<3 cm) NSCLC in whom surgery is contraindicated or refused and (2) patients with malignancy and limited (fewer than four) pulmonary metastases who are not candidates for surgical metastasectomy and have documented control of their primary tumor. For those with limited pulmonary metastases, a potential survival benefit from successful treatment of their metastases should exist to consider these patients for thermal ablation. Because many of these same patients are also candidates for external beam radiation using stereotactic techniques, the decision for nonsurgical candidates to use one or both techniques, if available, is made by a multidisciplinary group in consultation with the patient. Additional, less common indications for thermal lung ablation are listed in [Table 19-3](#).

There are several relative or absolute contraindications to performing image-guided thermal ablation of the lung. A patient's inability to cooperate for a prolonged (1½ hours) procedure on the CT table, despite the use of conscious sedation, can be managed by the use of general anesthesia with airway maintenance. Coagulopathy is a particular concern with cryoablation, which tends to induce local bleeding as a result of the freezing and thawing of tissue inherent to this technique. For these reasons any bleeding diathesis should be corrected before thermal ablation. Lesions that are immediately adjacent to the heart, aorta, superior vena cava, trachea, or esophagus are not amenable to thermal ablation, due to concern for damage to these structures.

Additionally, thermal ablation of lesions adjacent to larger intrathoracic vessels may not be adequately heated (RF ablation, microwave) or frozen (cryoablation) because flowing blood in these vessels produces a "heat sink" effect, whereby the temperatures in the part of the lesion nearest the flowing blood does not reach the temperature required to produce a cytotoxic effect and coagulative necrosis, and therefore the perivascular component of the tumor remains viable following ablation. Patients with pacemakers or implantable cardioverter-defibrillators are able to undergo RF ablation, but due to possible electromagnetic interference from the RF waves emitted from the ablation probe, these patients should be reprogrammed by an electrophysiologist for the duration of the procedure to avoid possible cardiac device malfunction.

The procedure of performing RF ablation is similar to the other two approved thermal treatment methods. The patient is positioned as if undergoing CT-guided TNB, with the anticipated puncture site placed nondependently. Because RF ablation involves electrical current extending from the probe into the surrounding tissues and through the body,

grounding pads are placed on the patients' thighs before the procedure to prevent the potential for skin burns by allowing for safe egress of electrical current from the body. For most lung lesions, a single needle probe is used and placed through the meridian of the lesion along its long axis. For treatment of lesions smaller than 2.5 cm, a standard 14-gauge probe ablates approximately a 3- to 4-cm zone of tissue, which provides for effective treatment of the lesion, and a 1-cm zone of normal lung surrounding the lesion, which should treat any microscopic disease at the margin of the tumor. For lesions larger than 2.5 cm, or for irregularly shaped lesions that cannot be effectively treated using a single ablation application, multiple overlapping ablation zones with repositioning of the needle between applications can be performed, although some radiologists prefer multi-tined probes or clustered electrodes that are designed to provide a larger ablation zone.

For RF ablation using a feedback algorithm to monitor impedance, intratumoral temperature, and electrical current, the needle is attached to a generator and conducts an alternating current at the frequency of radio waves (460 to 500 kHz) through the distal 3 cm that has been placed through the lesion to be treated. A 12-minute cycle is typically administered, during which current flows intermittently through the distal 3 cm of the needle. Impedance is monitored, and temperatures are measured to confirm adequate heating of tissues to ensure tumor death and a surrounding zone of lung necrosis. Ideally the temperature measured by the electrode within the tumor following the ablation cycle exceeds 50° C, a temperature at which cells die within minutes. Successful RF ablation produces a zone of ground-glass opacity surrounding the lesion and needle electrode on CT scans obtained immediately following ablation ([Fig. 19-15](#)). After one or more cycles have produced an adequate ablation zone as determined on CT, the needle is removed and the patient is managed as for TNB.

Multiple series detailing CT-guided RF ablation of unresectable early-stage lung cancer and limited pulmonary metastatic disease have shown the procedure to be safe with an acceptable complication rate.⁴⁸⁻⁵⁰ The most common complications include pneumothorax in 30% to 50% of patients, with 10% to 20% requiring catheter drainage.⁵¹ For lesions situated along the outer edge of lung, pain typically develops either during the ablation procedure or within 5 days of treatment, because RF ablation induces significant tissue infarction and secondary parietal pleural irritation. Twenty percent of patients will develop a pleural effusion, again most commonly when treating peripheral lesions, although most remain small and do not produce respiratory compromise or require drainage.

Although no randomized controlled trials have yet compared RF or other thermal ablation procedures to standard treatment therapies, such as surgery and radiation therapy, several series have shown 2-year survival rates of 50% to 60% for treatment of stage I NSCLC ([Fig. 19-16](#)) and approximately 70% for RF-treated colorectal metastases in selected patients, when lesions are 3 cm or smaller in diameter.⁵²⁻⁵⁴ The majority of recurrences are local and are directly related to mean tumor diameter, with lesions larger than 3 cm showing significantly higher recurrence rates and lower overall and disease-specific patient survival than those less than 3 cm in diameter.⁵⁵

Figure 19-15 CT appearance immediately following radiofrequency ablation of a pulmonary lesion. **A**, Chest CT displayed in bone windows with the patient prone during radiofrequency ablation of a solitary 3.5-cm metastasis from urothelial carcinoma shows two ablation probes (*arrows*) used to create a large ablation zone. **B**, Repeat CT scan following ablation shows a large halo of ground-glass opacity (*arrowheads*) encompassing the treated lesion (*asterisk*).

Figure 19-16 Long-term success of radiofrequency ablation for T1a non-small cell carcinoma of lung. **A**, Unenhanced CT displayed in bone windows performed through the upper lobes during radiofrequency ablation shows the electrode (*arrow*) placed through the left upper lobe nodule known to reflect a non-small cell lung carcinoma. **B**, CT scan 5 years following ablation shows a linear scar (*arrowhead*) at the site of the previous nodule.

PREOPERATIVE CT-GUIDED LOCALIZATION FOR VIDEO-ASSISTED THORACIC SURGERY NODULE RESECTION

INDICATIONS AND CONTRAINDICATIONS

With the increased detection of small pulmonary nodules on multidetector chest CT examinations, there is a concomitant increase in the need for pathologic diagnosis of those lesions too small to characterize as definitively benign or to sample accurately with TNB. The most common clinical scenario is the patient with a small lung nodule or nodules and a known primary thoracic or extrathoracic malignancy in whom the diagnosis of metastatic disease must be excluded. A patient with a solitary small lung nodule in whom wedge resection would provide both diagnostic information and potential therapeutic benefit may also be considered for VATS resection.

Most solid nodules 1.5 cm or smaller in the lung periphery (i.e., within 1.5 cm of the costal or diaphragmatic

pleural surface) can be successfully identified and resected at VATS. In certain patients with lesions smaller than 10 mm or with subsolid nodules, preoperative needle localization may aid the surgeon in identifying nodules intraoperatively. This facilitates successful intraoperative resection of these lesions, particularly if the nodule is greater than 1 cm from the visceral pleural surface and will be difficult to identify intraoperatively.

The preoperative patient preparation and basic technique of marking subpleural nodules for VATS resection is similar to that for TNB. The procedure is typically performed under CT guidance and is coordinated with the operating room so that the patient proceeds directly from radiology to the preoperative holding area and operating room immediately following image-guided localization.

The patient is positioned as if for performance of a CT-guided TNB, with the planned needle approach being the shortest distance between the nodule and the costal pleural surface. This aids the surgeon in using the localizing needle or wire to palpate the subpleural nodule intraoperatively and resect the least amount of normal lung along with the lesion to be removed. Rarely, a biopsy of a small

Figure 19-17 CT-guided needle localization of small peripheral nodule for video-assisted thoracic surgery resection. **A**, CT displayed in lung windows performed through the mid chest with the patient in prone position shows a 3-mm left lower lobe nodule (arrow) with the guide needle in the posterior chest wall (black arrowheads). **B**, Repeat scan following deployment of hook wire shows the wire with its tip (arrowhead) deep to the nodule (arrow). The lesion was successfully identified and resected intraoperatively.

nodule is attempted before the localizing procedure so that a VATS planned for diagnosis can be canceled if the TNB recovers a specimen with positive cytologic results or can proceed if the TNB is nondiagnostic. For patients in whom the VATS resection will be performed regardless of the preoperative diagnosis, only a localization procedure is performed. Ordinarily, conscious sedation is used as for TNB.

Although several differential techniques have been detailed for marking small peripheral nodules to aid VATS resection, most describe placing a needle through the nodule with a hook wire deployed through the needle and positioned with the hook deep to the nodule and left in position to aid resection in the operating room (Fig. 19-17).⁵⁶ A dressing is then applied to the skin and the patient transferred to the operating room for VATS.

Published success rates from multiple series detailing preoperative localization before successful VATS resection of peripheral nodules are generally around 90%.^{56,57} Even when a wire becomes displaced following deployment, the puncture site at the visceral pleura is usually visible intraoperatively and helps guide the surgeon to successful resection. Pneumothorax develops in approximately 10% of patients but rarely leads to wire displacement and is easily managed because the patients invariably proceed to thoracoscopy where a pneumothorax is induced as part of the operative procedure.

Key Points

- The most common indications for performing trans-thoracic needle biopsy include the definitive pathogenic diagnosis of a solitary pulmonary nodule, mediastinal mass, enlarged lymph node, chest wall mass, or pleural mass or thickening.
- Early-stage parapneumonic effusions, particularly those that are free flowing or unilocular, are amenable to successful image-guided catheter drainage using computed tomographic or ultrasonographic guidance, often with use of intrapleural fibrinolytic agents.

- Catheter drainage, with or without pleural sclerosis, provides effective treatment of symptomatic, recurrent malignant pleural effusions.
- Small-bore catheter drainage is a particularly effective treatment for iatrogenic pneumothorax, with success rates exceeding 85%.
- When indicated, catheter drainage for lung abscesses should be performed under computed tomographic guidance, placing the catheter in that part of the abscess closest to the pleural surface, ideally avoiding traversal of normal lung.
- Image-guided radiofrequency ablation of lung tumors is most effective for lesions less than 3 cm in diameter, with higher recurrence rates and lower overall survival for patients with lesions exceeding 3 cm.
- Needle-wire localization of lung nodules before video-assisted thoracoscopic surgical resection is most useful for lesions 1 cm or smaller and more than 1 cm from the pleural surface.

eFIGURE IMAGE GALLERY

Figure 19-1 Transthoracic needle biopsy complication: intercostal artery laceration resulting in hemothorax. Frontal chest radiograph (A) shows two nodular opacities (arrows) projected over the left lung base. Axial prone chest CT during percutaneous needle biopsy (B) shows the needle tip within a left lower lobe nodule (single arrowhead). The other nodule seen at chest radiography (also in A) is visible in the lingula (arrow). Hemorrhage is seen (arrowheads) deep to the lesion undergoing biopsy. Note that the point of needle entry into the thorax is inferior to the rib. Frontal chest radiograph performed several hours after the biopsy was completed (C), when the patient began to complain of chest pain and shortness of breath, shows extensive new left base opacity consistent with a combination of pleural effusion and adjacent consolidation. Axial unenhanced chest CT performed to assess the new chest radiographic findings (D) shows high-attenuation material in the left posterior thorax (asterisk), consistent with hemothorax. These findings suggested the possibility of intercostal artery laceration. Selective intercostal artery angiogram (E) shows the intercostal artery (arrowheads) that was injured and documents the presence of active extravasation (arrows) from this vessel. A pigtail catheter is visible at the far image right, and the catheter in the aorta is visible at the far image left, projected over the left paraspinal region. Note the relationship of the intercostal artery on this image—midway between the posterior thoracic ribs. Selective intercostal artery angiogram (F) following intercostal artery coil embolization (arrow) shows cessation of active extravasation from the injured vessel (arrowheads). DOCUMENTATION**TRAINING****ADVANTAGES AND DISADVANTAGES****INTRODUCTION**

Thoracic application of ultrasonography can be broadly divided into lung and pleural imaging. Additional applications designed for the evaluation of patients with dyspnea include vascular scanning for the diagnosis of lower limb deep venous thrombosis and basic ultrasonography of the heart. Furthermore, ultrasonography provides visual guidance for interventions in the pleural space. Instead of being considered as an optional thoracic imaging modality, bedside ultrasonography is increasingly seen as an extension of physical examination in the clinical evaluation and management of patients.¹

Ultrasonography continues to revolutionize pulmonary medicine by extending bedside diagnostic capabilities. Concerns remain regarding the medicolegal implications of errors in image interpretation. However, the utility of ultrasonography is gradually making the converse true as well: it is increasingly inexcusable not to use ultrasonography.^{2,3} Therefore it appears inevitable that ultrasonography will become established in the standard curriculum of pulmonary training.

BASICS OF ULTRASONOGRAPHY**ULTRASOUND PHYSICS**

Ultrasound is nonaudible sound energy used for medical applications in a frequency range of 2 to 20 MHz, frequencies that have been found to provide the best combination of penetration and resolution in the body. These frequencies are more than 1000 times greater than the audible range of sound, which ranges up to only 20 kHz. As ultrasound waves travel through tissue, they undergo attenuation and are also deflected by scattering, refraction, and reflection; it is the reflection of the waves that forms the basis of the ultrasonographic images. Reflection depends on the difference in sound transmission characteristics of the tissue, or the impedance, which is a measure of the resistance to propagation of sound waves from one medium to another.

At the boundary between two tissue structures with different impedance (i.e., an impedance mismatch), an ultrasound pulse is partially reflected. The greater the difference in acoustic impedance, the greater the strength of the reflected ultrasound signal will be. The difference in impedance between air and tissue is greatest, and thus almost all energy is reflected back; a coupling gel is necessary to remove all air from between the transducer and the skin to allow ultrasound energy to enter the body. The more minor differences in impedance between different body tissues allow partial reflection of waves that impart information about the location and characteristics of the tissues. Signal processing of the reflected energy into a gray-scale image on a screen forms the basis of ultrasonographic technology. (Table 20-1 provides a glossary of ultrasonographic terminology.)

The ultrasound pulse is generated by the piezoelectric crystals within the transducer probe. When an alternating current is applied, these crystals vibrate to convert electrical energy into mechanical energy and produce an emitting pulse. After the pulse is transmitted, the system awaits the return of reflected signals, which are received by the same piezoelectric crystals in the transducer. Returning ultrasound energy provides two types of information: the amplitude of the signal, which indicates how much energy is reflected, and the timing of the returning signal, which is related to the distance of the target from the emitting probe.

ULTRASONOGRAPHIC MODES

The processing of the reflected signals determines the type of image seen. In the A-mode (or *amplitude* mode), the received amplitude of energy from the transducer is displayed as peaks or waves shown at the distance determined by the depth of the image. This mode is not used currently in thoracic ultrasonography. With the B-mode (or *brightness* mode), the amplitude of energy is instead displayed as spots of different brightness, so that a series of B-mode images can be used to produce a conventional two-dimensional ultrasonographic image. In the M-mode (or *motion* mode), the image of a particular object is traced by capturing a

Table 20-1 Glossary of Ultrasonographic Terminology

Acoustic enhancement	An artifact showing an increase in echogenicity in a region distal to a fluid collection.
Acoustic impedance	Defined as the ratio of sound pressure to flow. A measure of the “resistance” of the medium to the transmission of sound waves from one tissue to another. The difference in acoustic impedance (mismatch) between two tissues determines the reflection of waves at the interface.
Acoustic shadow	Anechoic area behind bony structures.
Acoustic window	Pathway of an ultrasound beam between the probe and the target.
Alveolar interstitial pattern (or syndrome)	Multiple B-lines that signify the presence of thickened interlobular septa. This sign is defined by at least three B-lines in any single intercostal space and in at least two scanning zones of the thorax.
Attenuation	The progressive reduction of amplitude and intensity of a transmitted signal as it moves through a medium.
Artifacts	Images created by physical effects on sound wave propagation not reflecting the presence of actual tissues.
Artifact lines	
Comet-tail artifacts	Vertical hyperechoic lines arising from the pleural line (include B- and Z-lines).
B-lines	Comet-tail artifacts that spread all the way to the edge of the screen without fading.
Z-lines	Comet-tail artifacts that fade quickly without reaching the edge of the screen.
Other Lines	
A-lines	Horizontal hyperechoic echoes of the pleural line.
Doppler	Technique for imaging moving particles by the detection of a change in the frequency of the reflected ultrasound energy.
Echogenicity	
Hyperechoic	An appearance that is brighter or more white than that of normal solid organ structures such as the liver or spleen, which are considered isoechoic.
Hypoechoic	An appearance that is darker or more black than that of normal solid organ structures.
Anechoic	An appearance that is black and without echoes.
Lung sliding	The “to-and-fro” twinkling movement of the lung during respiration as it slides past the chest wall at the pleural line.
Modes	The means by which reflected ultrasound energy is displayed on the screen. In each case, the time for the energy to be reflected from an object determines the depth of the resultant image on the screen.
A-mode	Amplitude mode—reflected energy is shown as peaks of different size; not currently used in thoracic ultrasonography.
B-mode	Brightness mode—reflected energy is displayed as areas of different brightness; used to generate the standard two-dimensional ultrasonographic image.
M-mode	Motion mode—reflected energy is shown as areas of brightness traced from left to right on screen with time on the x-axis, used as an adjunct to B-mode.
M-mode signs	
Sinusoid sign	A hyperechoic sinusoidal line deep to a pleural effusion that represents movement of the visceral pleura with respiration adjacent to a pleural effusion.
Seashore sign	A grainy “sandy” image with a few horizontal lines denoting the “sea” at the top, a sign that represents aerated lung.
Stratosphere sign	A series of prominent horizontal lines that represents a pneumothorax.
Lung point	A sudden transition from a seashore to a stratosphere sign, representing the fleeting appearance of aerated lung expanding in inspiration into a pneumothorax. A positive ultrasonographic sign for pneumothorax.
Phased array probes	Probes that can steer ultrasound beams electronically by pulsing of transducer elements in sequence (phases). This allows a highly focused ultrasound beam to scan like a searchlight through tissue before a composite B-mode image is assembled.
Pleural line	Horizontal hyperechoic line that corresponds to the interface between the lung and the chest wall.
Resolution	The ability to display two tissue interfaces that are close to each other as separate images by ultrasonography.
Time-variable gain	An amplification of reflected ultrasound energy proportional to the timing of the returning signals to enable deeper objects to be as bright as those closer.

B-mode image as it sweeps across the screen against a time axis. This provides a single image in which relative positions of images are shown against time on the x-axis. The B-mode is the standard mode for all studies, and the M-mode is usually used as an adjunct, especially when B-mode findings are equivocal.

TRANSDUCERS

Thoracic ultrasonography typically uses the 3.5- to 5-MHz frequency range, which provides the optimal compromise between spatial resolution and depth of penetration for thoracic indications. Higher frequencies improve resolution but limit the depth of imaging; lower frequencies visualize with less resolution but to a greater depth. Thoracic ultrasonography generally uses curvilinear, or microconvex,

probes, which employ a curved surface to create a scanned field that is wider than the footprint of the probe, producing a sector or fan-shaped image; small footprints can also be achieved with phased array probes with electronic steering. Small footprints enable better access through the narrow acoustic windows available between ribs through which the beam can access deeper tissues. Compared to linear probes, curvilinear transducer probes have reduced lateral resolution; however, the resolution is acceptable for discriminating the relative sizes of structures imaged in the chest.

DOPPLER ULTRASONOGRAPHY

Doppler imaging is used to detect motion. Doppler imaging is based on the principle that the frequency of sound increases as the source of sound moves toward an observer

and decreases as the source of sound moves away. In pulsed wave Doppler, a pulse is transmitted and the change in frequency of the returning echo is measured at a certain time. Traditionally, red denotes objects moving toward the probe and blue on the screen denotes objects moving away from the probe. Optimal imaging for color Doppler is obtained when the transducer is directed *parallel* to the flow of the target; in contrast, for B-mode and M-mode ultrasonography, optimal imaging is produced when the transducer is directed *perpendicular* to the target.

ULTRASONOGRAPHIC IMAGE ACQUISITION

POSITIONING OF PATIENTS AND PROBE

In a free pleural space without septations, effusions will collect in the dependent parts of the thorax, whereas free air will collect in superior, nondependent locations. Therefore the positions of the patient and ultrasonographic probe are crucially important to evaluating these indications. In most thoracic evaluations the patient is examined sitting upright. Patients who are ill may be examined in the supine or lateral decubitus position, but this must be taken into consideration when images are interpreted. By abducting the arm, the intercostal space distance can be increased to provide a larger acoustic window. For a systematic evaluation, the hemithorax should be examined in each of the four zones demarcated by the parasternal, anterior axillary, and posterior axillary line^{4,5} (Fig. 20-1). The patient is then asked to sit upright and is scanned along the posterior paravertebral line. Every scan must visualize the diaphragm inferiorly. For better access to the posterior thorax, supine patients who cannot sit up can be moved to the lateral edge of the bed.

Figure 20-1 Four zones of chest ultrasonography. Systematic approach to ultrasonography of the chest begins by evaluating the hemithorax in each of the four zones demarcated by the parasternal (PSL), anterior axillary (AAL), and posterior axillary (PAL) lines.² The operator should obtain at least one representative intercostal scan from each region. The patient is then asked to sit upright and is scanned along the posterior paravertebral line (not shown).

SCAN/PROBE ORIENTATION

Longitudinal scans through the intercostal spaces (i.e., parallel to the long axis of the body) are preferred to transverse scanning both because of convention and because a longitudinal image will include the diaphragm for ease of reference. To maintain orientation of the probe and the resulting image, the transducer probe has a ridge or groove. With the groove oriented toward the head of the patient, the resultant image will show the cranial direction to the left of the screen. Superficial structures will be at the upper part of the screen and deep structures at the bottom of the screen (Fig. 20-2).

PROBE HANDLING

The probe is held in the dominant hand as one would hold a pen, with the forefinger on the orientation groove. The examiner's hand rests against the patient's skin as a support to stabilize the transducer. The probe is moved from intercostal space to intercostal space and moved transversely within intercostal spaces. For this movement, called "transducer movement," the probe is held perpendicular to the skin. For two other movements, the probe is tilted: "transducer tilt" describes the rocking movement of the probe at any particular position to obtain images along the same tomographic plane and "transducer angulation" to obtain images in adjacent planes. Tilt and angulation are fine movements, and too much of either can result in loss of contact with the skin, causing a poor image. Because air forms an almost impermeable barrier to ultrasound, air trapping is minimized by using a water-based coupling gel and by holding the probe firmly against the skin. The probe must be kept still during image acquisition to prevent confusion between the movement of the probe and dynamic signs within the thorax.

IMAGE ACQUISITION

Two parameters need to be adjusted for optimal acquisition of the images: depth and gain. The depth of the field is set according to the needs of the ultrasonographic

Figure 20-2 Pleural effusion. In this B-mode image, an anechoic pleural effusion is bordered by the hyperechoic diaphragm and an isoechoic atelectatic lung. The green dot at the top of the screen indicates that the cranial orientation is to the left of the screen.

examination: a 10-cm depth will usually suffice for most thoracic investigations. Less depth magnifies the image and allows clearer visualization of the near field, as, for example, for evaluating the pleural surface for lung sliding. Deeper penetration may sometimes be needed to define boundaries of the image of interest. The gain is set to amplify signals relative to background noise. Increasing the gain makes an image whiter, whereas decreasing the gain makes the image blacker. Time-variable gain enables the operator to amplify ultrasound signals proportional to the depth to make deeper structures appear as bright as more superficial structures. Because solid organs such as the normal liver are considered to be of intermediate density (isoechoic), gain can be adjusted with reference to the liver image to make it gray on the screen; other tissues can then be evaluated in comparison to this standard gray image. Although noise filters can improve the quality of imaging solid and liquid structures, the use of such filters can also obliterate the signal artifacts that are crucial to diagnostic analysis of aerated lung.

IMAGE INTERPRETATION

Two types of images are visualized by ultrasonography, either anatomic structures or artifacts.⁶ Anatomic structures are identified based on their location and echogenicity. Echogenicity of body structures can be referenced to solid organs such as the liver, which are made to appear gray or isoechoic on the screen. Uncomplicated fluid collections appear darker than these solid organs and are termed “hypoechoic”; if they appear black, they are termed “anechoic.” Air appears white and is hyperechoic. The homogeneity or heterogeneity of echoes also contributes to the recognition of different tissues.

Artifacts are images that do not correspond to specific anatomic structures but provide useful information if properly recognized. Examples of artifacts are acoustic shadows, acoustic enhancement, and reverberation echoes (see [Table 20-1](#)). Unlike anatomic structures, artifacts tend to move with the movement of the probe and converge toward the near field at the top of the screen. *Acoustic shadows* are anechoic regions that lie behind bony structures such as ribs. Because acoustic shadows provide no ultrasound information, the transducer probe should have an appropriately small footprint to transmit ultrasound pulses between the bony structures and thus avoid them. *Acoustic enhancement* is a hyperechoic region (lighter than liver) located distal to a fluid collection; the enhanced region distal to the fluid should not be mistaken for another tissue structure. *Reverberation echoes* are alternating dark and white lines produced when ultrasound beams reflect back and forth between two surfaces, often at an air–soft tissue interface. These echoes produce multiple-copy images seen at different depths depending on the number of times the beam was reflected ([Fig. 20-3](#)).

LUNG ULTRASONOGRAPHY

Competence in lung ultrasonography involves knowledge of terminology of ultrasound signatures in the thorax, as well as identification of consolidated lung and air artifacts.⁷

Figure 20-3 Normal lung. In this B-mode image of normal lung, the pleural line and A-lines are indicated. A-lines are echoes of the pleural line and indicate the presence of an air–pleural interface, whether the air is in aerated lung or free in the pleural space (e.g., pneumothorax).

([Table 20-2](#) lists lung ultrasonographic signs, and [Table 20-3](#) compares lung and pleural ultrasonographic competencies.) Key diagnoses that can be made include pneumothorax, pulmonary consolidation, and pulmonary edema.

NORMAL LUNGS

“Lung sliding” is the key sign used to identify normal lungs.⁶ To identify lung sliding, one first identifies the “pleural line” as a horizontal hyperechoic line located approximately 0.5 cm below the skin surface corresponding to the interface between the lung and the chest wall.⁸ The pleural line is framed by anechoic shadows caused by the ribs. A-lines are deeper horizontal lines that are reverberation echo artifacts of the pleural line⁸ (see [Fig. 20-3](#)). Once these lines are identified, lung sliding is seen as the to-and-fro twinkling and movement of the lung adjacent to the pleural line in rhythm with inspiration and expiration ([Video 20-1](#)). The image above the pleural line on the screen is motionless. Therefore lung sliding identifies visceral pleura sliding over parietal pleura. An M-mode image of this view will show up as a grainy pattern that recedes distally and is termed the “seashore sign”⁹ ([Fig. 20-4A](#)).

Lung sliding is an important sign for identifying normal lung, but it is dependent on technical issues and interpretation. For example, the sign may not be detected with low-frequency probes below 2.5 MHz or if the depth is set too deep.⁹ In addition, the amplitude of lung sliding will decrease at the apex of the lung, where movement of the lung is less. Lung sliding can be mimicked by accessory respiratory muscle contractions, although, unlike lung sliding, muscle movement will appear superficial to the pleural line. Lung sliding can also be absent in pathologic conditions in which lung motion is impaired, such as pleurisy, pleurodesis, pneumothorax, subcutaneous emphysema, apnea, jet ventilation, extreme bronchospasm, extensive pneumonia, and the *acute respiratory distress syndrome* (ARDS).⁸ Thus the absence of lung sliding may not be useful, whereas its presence is effective in ruling out many of the abnormalities of the lung.

Table 20-2 Ultrasonographic Signs of Normal Lungs and Pulmonary Pathologic Conditions

Condition	Ultrasonographic Findings
Normal lungs	Lung sliding A-lines 1-2 B-lines Seashore sign on M-mode
Pneumothorax	Absence of lung sliding sign A-lines Absence of B-lines Stratosphere sign and lung point on M-mode
Lung consolidation/atelectasis “Alveolar pattern”	Isoechoic hepatization of lung with white linear or branched air bronchograms Vascularity within consolidation preserved on color Doppler Atelectasis may present with elevated hemidiaphragm and black (fluid-filled) bronchograms
Pulmonary edema	Diffuse and multiple B-lines with homogeneous distribution Lung sliding present Normal pleural line Bilateral anechoic pleural effusions Evidence of left ventricular dysfunction on echocardiography
ARDS/pulmonary fibrosis “Alveolar interstitial pattern”	Diffuse and multiple B-lines with heterogeneous distribution Reduced or absent lung sliding Abnormal pleural line (irregular thickening or fragmentation)
Diaphragm paresis or paralysis	Diaphragm moving < 5 mm or paradoxically in inspiration Thinning of the diaphragm or loss of normal thickening with inspiration Loss of lung sliding sign
Pulmonary embolism	Pulmonary infarcts appearing as peripheral wedge-shaped consolidation with diminished vascularity on color Doppler Ipsilateral hyperechoic (hemorrhagic) effusion Supportive signs from ultrasonography of the heart (acute cor pulmonale) and compression vascular sonography of lower limbs (proximal deep venous thrombosis)

ARDS, acute respiratory distress syndrome.

Table 20-3 Required Competencies for Lung and Pleural Ultrasonography⁴⁸

Lung Ultrasonography	Pleural Ultrasonography
1. Knowledge of ultrasonographic signs: lung sliding, A-lines, B-lines, lung point 2. Identification of normal lung 3. Identification of signs that rule out and rule in pneumothorax 4. Identification of consolidated lung 5. Identification of alveolar interstitial pattern 6. Recognition that the absence of lung sliding and B-lines is a sensitive, but not specific, sign for pneumothorax	1. Identification of a pleural effusion as defined by typical anatomic boundaries 2. Identification of dynamic signs of pleural effusions 3. Identification of ascites and adjacent organs such as the liver, spleen, kidney, and heart 4. Characterization of pleural fluid based on echogenicity, homogeneity, and presence of debris/septations 5. Semiquantitative assessment of volume of pleural effusion 6. Identification of solid pleural lesions and pleural thickening 7. Recognition of limitations of ultrasonography in identifying pleural fluid

Figure 20-4 Normal lung compared to a pneumothorax. In these M-mode images, a normal lung is seen showing the seashore sign (A) next to a pneumothorax showing the stratosphere sign (B). The seashore sign is recognized by the grainy texture and is distinguished from the stratosphere sign, in which the grainy quality is absent and only the horizontal lines are seen. Top, The B-mode images from which the M-mode images were generated.

PNEUMOTHORAX

Ultrasonography is more accurate than supine anteroposterior chest radiographs in the diagnosis of pneumothorax.¹⁰ Pneumothorax itself has few positive findings; it is generally identified by the absence of the signs of normal aerated lung. As described earlier, aerated lung is noted by the presence of the lung sliding sign; the lung is also noted by artifacts called “comet tails,” including B-lines and Z-lines, which are vertical hyperechoic lines that arise from the pleural line and move in synchrony with lung sliding.⁹ B-lines spread from the pleural line all the way to the edge of the screen without fading.⁹ These lines are the most important of the comet tails, and their presence or absence can help guide the diagnostic value of ultrasonography (Video 20-2). Z-lines are similar but, unlike B-lines, fade quickly and do not reach the periphery of the screen.⁹

In any ultrasonographic examination for pneumothorax, the nondependent part of the hemithorax needs to be scanned. In a pneumothorax, A-lines representing reverberation echoes of the pleural line will still be seen, showing that an air-tissue interface is present, but there will be no movement of the lung sliding at the pleural line and no evidence of B-lines^{11,12} (Video 20-3). In the appropriate clinical context, the absence of lung sliding and B-lines indicates the presence of pneumothorax with a reported 100% sensitivity and 96.5% specificity.¹³ On the other hand, the presence of the lung sliding sign basically excludes a pneumothorax, with a reported 100% negative predictive value.¹¹ In a pneumothorax, multiple accentuated A-lines may be seen, and this can be captured on M-mode as a series of stratosphere-like horizontal lines (i.e., the stratosphere sign)⁹ (Fig. 20-4B). The horizontal lines seen in the stratosphere sign, which are characteristic of free air, can be contrasted with the grainy pattern prominent in the seashore sign of normal aerated lung (see Fig. 20-4A). A pneumothorax can be grossly quantified as large if the loss of both lung sliding and comet tails extends to dependent parts of the thorax. The sudden and fleeting appearance of lung sliding and B-lines in an area where they were previously absent may indicate aerated lung expanding intermittently into a moderate-sized pneumothorax. This fleeting appearance if captured on M-mode is termed the “lung point” and has been reported to have 66% sensitivity and 100% specificity for the diagnosis of a pneumothorax.¹⁴ These ultrasonographic signs when used in combination may diagnose occult pneumothoraces not detected on supine chest radiographs¹⁵ and are useful in the evaluation of patients after procedures such as central venous catheter placement, transbronchial lung biopsy, and chest tube clamping. The presence of a pneumothorax must be strongly suspected if B-lines that were present before the procedure are not detected after the procedure.

Errors that can lead to a failure to diagnose pneumothorax include failure to scan in the nondependent parts of the thorax, failing to scan longitudinally, excessive use of noise filters, and an unsteady scanning hand that may give the false impression of lung sliding. A false diagnosis of pneumothorax may arise in patients with *chronic obstructive pulmonary disease* (COPD), lung bullae, and adhesions, which may mimic pneumothorax on ultrasonography.⁴ In patients

with COPD the specificity of the diagnosis of pneumothorax is reduced to 71% even among experienced operators, indicating that additional imaging studies are required to confirm a pneumothorax in such patients.¹⁶

LUNG CONSOLIDATION/ATELECTASIS

Alveolar consolidation can be identified on ultrasonography if the area of consolidation extends to the visceral pleura; if not, the intervening aerated lung will generate artifacts that make the diagnosis difficult. In alveolar consolidation, lung sliding will be abolished and a tissue pattern similar to the liver will develop because of the consolidation and “hepatization” of the lung. This sign, which has been termed the “alveolar syndrome” in some studies¹⁷ and is here referred to as the “alveolar pattern,” can be due to a variety of causes, including pneumonia, atelectasis, contusion, malignancy, and infarction. Discrimination between these diagnoses may be attempted with further ultrasonographic analysis, including assessment of the deep margins of consolidation, identifying air or fluid bronchograms, and evaluating the vascular pattern within the consolidation using color Doppler.⁴

In patients who have pneumonia, the superficial boundary of consolidated lung is usually regular and conforms to the visceral pleura, whereas the deep border is irregular and faded and varies with respiration.^{17,18} Comet-tail artifacts may also be seen at this far-field border.¹⁸ Air bronchograms may be seen as hyperechoic (white) branched or linear shadows that may vary with respiration^{19,19a} (Fig. 20-5). Air trapped in the distal airways shows up as punctate white spots.²⁰ On color Doppler, branching pulmonary blood vessels may be visualized within the area of consolidation.²¹ These signs together with the absence of a sinusoidal pattern on M-mode that would indicate lung motion give ultrasonography a diagnostic sensitivity of 90% and specificity of 98% in detecting consolidation when compared to *computed tomography* (CT) scans.²² A false-positive diagnosis of consolidation may result when complex echogenic pleural effusions or intrathoracic fat are mistaken for consolidation. The size of consolidation is typically smaller on ultrasonographic images than on chest radiographs because the peripheries of a pneumonic area are usually partially air filled.²³

Atelectasis is imaged by ultrasonographic scanning in a way similar to that for consolidation. In addition, intercostal spaces may be narrowed and the hemidiaphragm elevated. If air bronchograms are seen, they do not change size with respiration. If the bronchi are filled with fluid in a postobstructive atelectasis, then fluid bronchograms may be seen as anechoic linear shadows within the area of consolidation.²⁴ The features of peripheral lung malignancies with chest wall invasion and infarctions associated with pulmonary embolism are described in subsequent sections.

ALVEOLAR INTERSTITIAL PATTERN

The alveolar interstitial pattern (or syndrome) is a term used to describe multiple B-lines in multiple scanning zones of the thorax, a pattern that can be seen in various pathologic conditions such as pulmonary edema, ARDS,

Figure 20-5 Consolidated lung. In this B-mode image (A), subpleural consolidation with hyperechoic branched shadows (arrows) are shown that correspond to the air bronchograms seen on the adjacent CT scan of the same patient (B).

and pulmonary fibrosis. Whereas single B-lines are found in normal lungs as described, multiple B-lines have been shown to correlate to thickened interlobular septa.²⁵ To identify an alveolar interstitial pattern, one must see at least three B-lines in any single intercostal space and in at least two scanning zones of the thorax (see Fig. 20-1).^{4,26} Finding bilateral and diffuse multiple B-lines has a diagnostic sensitivity and specificity of 93% when compared to chest radiographs in the diagnosis of pulmonary edema.^{27,27a} The diagnosis can be confirmed by the disappearance of this finding with appropriate treatment of heart failure. This ultrasonographic pattern has been shown to correlate with N-terminal pro-brain natriuretic peptide levels.²⁸ The total number of B-lines in the anterior and lateral chest of supine patients has also been shown to correlate with both oxygenation levels and pulmonary artery wedge pressure.^{29,30}

The presence of bilateral anechoic pleural effusions can contribute to the diagnosis of pulmonary edema. Echocardiography at the same setting can assess left ventricular size and function to confirm the diagnosis and cause. A dilated left ventricle suggestive of volume overload can be identified on the parasternal long axis view at the left sternal border in the third to fifth intercostal space with the orientation groove pointing at the right shoulder. If there is a 5-mm or lower approximation of the anterior mitral valve toward the interventricular septum, the ejection fraction is likely to be normal. Rotation of the probe 90 degrees to point toward the left shoulder should produce the parasternal short axis view at the papillary muscle midsection. This view helps identify heterogeneous contractility suggestive of myocardial ischemia/infarction. Both long- and short-axis views also help the physician look at global left ventricular function. These are examples of qualitative assessments that can be made by physicians who have received the appropriate training and can provide accurate point-of-care diagnoses.³¹

Pulmonary fibrosis and ARDS can be mistaken for pulmonary edema because ultrasonography cannot distinguish between interlobular thickening due to edema and interstitial thickening due to inflammation or infiltration.²⁷ However, in ARDS and pulmonary fibrosis, lung sliding is

reduced or absent, the B-line pattern is inhomogeneous, and pleural line abnormalities such as irregular thickening and fragmentation may be detected.^{4,32} In addition, ARDS presents with patchy anterior consolidation and spared areas representing regions of normal lung.³² If a unilateral or focal alveolar interstitial pattern is found, the differential diagnoses include pneumonia, pneumonitis, atelectasis, contusion, infarction, and malignancy.^{4,33}

OTHER DIAGNOSES

Diaphragmatic function can be assessed via ultrasonography. This can be especially useful in evaluating patients with difficulties in weaning from mechanical ventilation. For such studies, to ensure diaphragm recruitment and avoid false-negative study results, patients should be placed on a spontaneous breathing trial. With inspiration the normal diaphragm moves caudally 10 to 15 mm.¹⁸ In the setting of diaphragmatic dysfunction, the movement of the diaphragm on inspiration may be less than 5 mm, and signs of lung motion such as lung sliding may be lost.¹⁸ Paradoxical movement of the diaphragm moving cranially during inspiration may also be seen. The normal diaphragm should be more than 2 mm thick at the zone of apposition with the rib cage and should thicken by more than 20% with inspiration³⁴ (Video 20-4). Thinning of the diaphragm at rest or a reduced thickening with inspiration suggests paralysis.³⁵ Normal thickening may predict success of weaning from ventilation.^{35a}

Pulmonary embolism is suggested by peripheral consolidation representing pulmonary infarction and by the detection of a unilateral pleural effusion, which may be hyperechoic due to hemorrhage. Pulmonary infarcts typically appear as round or triangular pleural-based lesions³⁶ with evidence of reduced vascularity on color Doppler.²³ Thoracic ultrasonographic findings can be supplemented by compression vascular sonography of the lower limbs to identify deep venous thrombosis, which can be detected in over 50% of patients with symptomatic pulmonary embolism.^{37,37a,37b} Venous ultrasonography is performed using a 5- to 10-MHz linear probe, which has higher

resolution than a thoracic probe. The supine patient is positioned with the thigh externally rotated and the knee flexed at 45 degrees. Transverse scanning starts at the common femoral vein proximal to the junction of the great saphenous vein and moves distally at 2-cm intervals along the superficial femoral vein and then the popliteal vein until its trifurcation into calf veins. Chronic, organized thrombus is echogenic and is seen lying within the vein (Video 20-5). Acute thrombus is hypoechoic and requires a compression maneuver for identification. Using the adjacent artery as a reference, the operator applies compression to the tissues overlying the vascular structures. In the normal setting the vein can be completely compressed, with the anterior and posterior walls apposing and the lumen obliterated, whereas there is only minimal deformation of the adjacent artery (Video 20-6). In the presence of thrombus, the vein will not compress or will compress only partially (Video 20-7). Compression ultrasonography performed by intensivists has a diagnostic sensitivity and specificity of 86% and 96%, respectively.³⁸ If the compression ultrasonographic diagnosis remains uncertain, then Doppler evidence of absence of flow, especially during augmentation by calf compression, can be used.³⁹

Acute cor pulmonale caused by pulmonary embolism can be diagnosed by identifying right ventricle dilatation and pressure overload.⁴⁰ When ultrasonography is used to evaluate the heart, the operator must be trained in the recognition of ventricle size and function in different views. On the apical four-chamber view, in normal patients the left ventricle forms the apex of the heart and the right ventricle is about 60% the size of the left. Right ventricular dysfunction can be identified by a dilatation of the right ventricle relative to the left and by identifying a dyskinesia of the interventricular septum caused by pressure overload. On the parasternal short-axis view, the septum flattens out and the right ventricle loses its normal crescent shape, instead taking on a D-shaped configuration. McConnell's sign (i.e., regional right ventricular dysfunction with akinesia of the mid-free wall but normal wall motion at the apex) is very specific for acute pulmonary embolism but has limited sensitivity⁴¹ (see Video 57-1).

Chest wall invasion by lung cancer may be assessed more accurately by ultrasonography than by CT scans, with sensitivity and specificity of 89% and 95%, respectively.⁴² Chest wall invasion is diagnosed by finding tumor growth across the pleura, invasion of the ribs, and absence of lung sliding. A high-frequency vascular probe may be needed to identify tumor invasion.¹ Subpleural tumors typically have heterogeneous echogenicity and distorted vascularity as seen on color Doppler imaging.^{23,43}

Airway diseases are not generally evaluated using ultrasonography. Although ultrasonography is of little diagnostic value in airway diseases, bronchospasm can be suspected in a breathless patient based on prominent A-lines and preserved lung sliding.^{44,44a} Unilateral main-stem bronchus intubation results in cessation of ventilation to one lung and consequently causes lung sliding on that side to be abolished. However, the lung may still be aerated, causing A-lines and the lung pulse sign of transmitted cardiac contractions to be retained.⁴⁵

Lung abscesses present as hypoechoic fluid collections within an area of consolidation with well-defined walls.⁴⁶ The irregular borders of consolidation about the pleura at an acute angle, and, in the center of the abscess, swirling fluid may be seen. Air-filled cavities will have echogenic foci within the abscess.¹ It may be difficult to distinguish a lung abscess from a pleural empyema, and a distinction between the two diagnoses can be important because of the implications for pleural drainage. Identification of vessels in the pericavitary consolidation using color Doppler has a specificity approaching 100% for peripheral lung abscesses. Conversely, the presence of septations and passive atelectasis are common findings in empyema.⁴⁷

ALGORITHMIC EVALUATION OF ACUTE DYSPNEA

Ultrasonography can be used in the evaluation of a patient with severe, new-onset dyspnea using an algorithmic approach called the *Bedside Lung Ultrasound in Emergency* protocol (i.e., the "BLUE" protocol) (Fig. 20-6). For this protocol the anterior chest is first scanned with the patient in

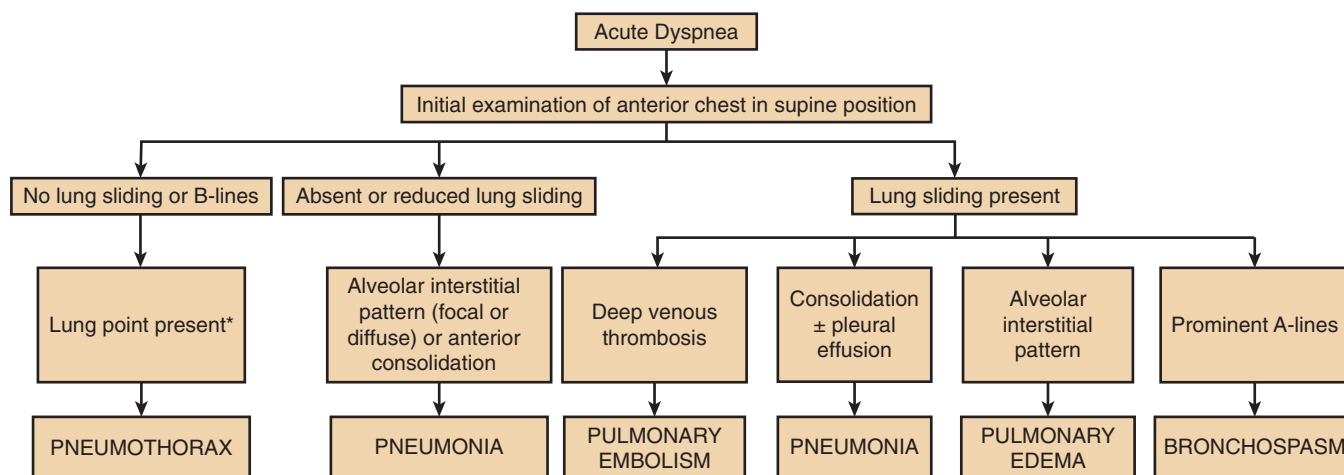

Figure 20-6 Algorithmic evaluation of acute onset, severe dyspnea showing possible diagnoses.⁴⁴ This stepwise approach has been termed the *Bedside Lung Ultrasound in Emergency* (BLUE) protocol. *If a lung point is not identified, other diagnostic approaches are advised to confirm or exclude pneumothorax.

the supine position.⁴⁴ Lung sliding is assessed, and then four patterns are sought: bilateral A-lines, bilateral alveolar interstitial pattern, and either unilateral alveolar interstitial pattern or consolidation. The diagnosis is then refined depending on the concomitant presence of pleural effusion, posterior consolidation, or deep venous thrombosis.⁴⁴ In patients presenting to the emergency department with acute dyspnea, there is a high degree of concordance between ultrasonography and chest radiographs for diagnoses such as pulmonary edema ($\kappa = 95.0\%$), pneumothorax ($\kappa = 85.5\%$), and consolidation ($\kappa = 70.0\%$).¹⁷ Goal-directed ultrasonography of the heart can supplement the evaluation by assessing cardiac causes of dyspnea. Right or left ventricular dysfunction as well as pericardial effusion can be excluded. Pericardial effusions are distinguished from pleural effusions on the parasternal long-axis view by location with respect to the aorta: pericardial effusions are situated anterior to the descending aorta (Video 20-8). Tamponade physiologic characteristics are identified by early diastolic collapse of the right ventricle, which is best seen on either the apical four-chamber or subcostal view. Certainly such diagnostic use of ultrasonography has great potential but also demands adequate training for proper interpretation.

PLEURAL ULTRASONOGRAPHY

Ultrasonography is extremely valuable for a variety of pleural indications (Table 20-4). Ultrasonography is more sensitive than chest radiography in diagnosing small pleural effusions and is especially effective in distinguishing effusions from lung atelectasis.⁷ Competence in pleural ultrasonography involves identification of a hypoechoic region surrounded by the appropriate anatomic boundaries, iden-

tification of the liver/spleen and other abdominal organs, recognition of dynamic features of pleural effusions, characterization of pleural fluid, semiquantitative assessment of effusion volume, and identification of pleural-based masses, as well as an understanding of the limitations of ultrasonographic scans of the pleura (see Table 20-3).⁷

PLEURAL EFFUSIONS

Pleural effusions are diagnosed either by using longitudinal scanning through the intercostal spaces or by using subcostal abdominal scanning to visualize the diaphragmatic pleura through the liver or spleen. Subcostal scans, which identify effusions in relation to the position of the diaphragm, spleen/liver, and atelectatic lung, are particularly useful when intrathoracic air (e.g., hydropneumothorax) prevents image acquisition via intercostal scans. Pleural effusions can be identified by using both static and dynamic signs.

Static signs for identifying pleural effusions are finding a hypoechoic region within the anatomic boundaries of the diaphragm caudally, the chest wall superficially, and the atelectatic lung at the bottom of the screen (see Fig. 20-2). Although the effusion is usually hypoechoic, echogenicity cannot be the sole criterion for identifying a pleural effusion. For example, whereas all transudative effusions and some exudative effusions are anechoic, anechoic regions can also be seen because of pleural thickening⁴⁸ or abdominal ascites. Alternatively, echogenic regions can be seen with complex pleural effusions such as hemothorax or empyema.

Dynamic signs used to identify pleural effusions include movement of the diaphragm adjacent to the effusion and of the lung within the effusion. The diaphragm is identified as a hyperechoic concave structure that descends with

Table 20-4 Ultrasonographic Signs of Pleural Pathologic Conditions

Pathologic Condition	Ultrasonographic Findings
Pleural effusion (free flowing)	Static signs show a usually anechoic collection that is bordered by the diaphragm, atelectatic lung, and the chest wall Dynamic signs include flapping of atelectatic lung in the effusion and diaphragm movement with respiration, allowing an effusion to be distinguished from ascites B-mode curtain sign showing intermittent appearance of lung expanding into the pleural effusion M-mode sinusoid sign showing visceral pleura motion adjacent to an effusion
Transudates	Anechoic collection
Exudates	Anechoic or echogenic collection If echogenic, can be homogeneous or heterogeneous
Complicated parapneumonic effusions/empyema	Heterogeneously echogenic collection Presence of septations Hematocrit sign
Malignant effusions	Heterogeneously echogenic collection Swirling debris Hematocrit sign Pleural thickening > 10 mm Diaphragmatic thickening > 7 mm Presence of pleural nodules
Mesothelioma	Hypoechoic and irregular thickening that covers large areas of pleura with indistinct borders
Pleuritis	Thick peel of tissue No mobile components (i.e., Doppler negative) Variable echogenicity Calcification seen as hyperechoic spots Visceral pleural inflammation associated with consolidation Any associated effusion tends to be multiloculated

inspiration and is bordered caudally by either the liver or the spleen, both isoechoic structures. The position of the diaphragm helps distinguish a pleural effusion from ascites in the hepatorenal recess, where the diaphragm and its movement will not be seen. Of note, caution must be used in interpreting subcostal images because the concave diaphragm has high reflective properties that can lead to acoustic enhancement artifacts that can be mistaken for consolidation.⁹ Another dynamic sign of pleural effusions that can help avoid these misdiagnoses includes the movement of the atelectatic lung seen as a “flapping” within the effusion (Video 20-9). In addition, sometimes on B-mode a “curtain” of aerated lung slides into and out of small effusions. If the diagnosis is equivocal on B-mode, additional information can be gained by using M-mode; in M-mode a pleural effusion can be identified by seeing the respiratory movement of the visceral pleura toward the chest wall as a sinusoidal pattern.⁹

Ultrasonographic characterization of pleural fluid is based on echogenicity and homogeneity. However, thoracentesis is still needed to distinguish transudates from exudates. In heterogeneous effusions the presence of internal echoes such as swirling debris or septations is highly predictive of either complicated parapneumonic effusions or malignancy^{49,50} (Videos 20-10 and 20-11). In immobile patients the cellular components may settle to create a bilayer with a more echogenic dependent component. This has been termed the “hematocrit sign” and can be seen in either hemothorax or empyema⁴⁸ (Video 20-12). During scanning, the pleura should also be carefully examined because pleural thickening of greater than 10 mm, pleural nodularity, and diaphragmatic thickening of greater than 7 mm have all been found to be highly suggestive of a malignant effusion⁵¹ (Video 20-13).

The use of ultrasonography to quantify the volume of pleural effusions has yet to be established in clinical practice. The size of the thoracic cavity, presence of loculations, position of the diaphragm, and degree of lung collapse all affect ultrasonographic measurements.⁵² Despite these limitations, in supine patients the distance of maximum separation of parietal and visceral pleura on ultrasonography has been shown to correlate better with the volume of thoracentesis drainage than measurements on lateral decubitus chest radiographs.^{52,53} For comparison of the size of the same effusion over time, the transducer and the patient must be in exactly the same position for each measurement.

SOLID PLEURAL LESIONS

Pleuritis is visualized as a thick and hypoechoic peel of tissue with no mobile components (i.e., Doppler negative).⁵⁴ Calcification within pleural fibrosis, indicating chronic inflammation such as previous tuberculosis, may be seen as hyperechoic spots but is usually challenging to detect because of adjacent aerated lung. Visceral pleural inflammation and thickening is associated with underlying consolidation.⁴⁸

Pleural carcinomatosis is visualized through the acoustic window provided by the adjacent effusion as either thickening or echogenic nodules of various shapes and sizes.⁵⁵ Malignant mesothelioma is seen as hypoechoic and irregular thickening that covers large areas of pleura with

indistinct borders. Nodules and chest wall invasion may also be detected in mesothelioma.⁴⁸ Benign pleural tumors such as chondromas and lipomas are both rare and more difficult to diagnose. They display varying ultrasound echogenicity, have distinct capsules, do not invade adjacent tissue, and have no associated pleural effusion.⁴⁸

THORACIC PROCEDURE GUIDANCE

Ultrasonographic guidance can be valuable in increasing the success and safety of thoracentesis. Ultrasonographically guided thoracentesis can obtain fluid in up to 88% of previously unsuccessful “blind” or nonguided cases.⁵⁶ In the majority of failed blind pleural taps, subsequent examination by ultrasonography has shown that the needle had been inserted subdiaphragmatically.^{56,57} By using ultrasonographic guidance, operators can avoid puncturing organs such as the lungs, liver, spleen, and heart. Ultrasonographic guidance can reduce the incidence of iatrogenic pneumothorax from 5% to 39% following blind thoracentesis to as low as 0% to 5.4%.⁵⁸⁻⁶³ With ultrasonographically guided thoracentesis, the rate of pneumothorax can be kept to as low as 1.3% even in patients on positive-pressure ventilation.⁶⁴

An ultrasonographically directed thoracentesis is performed by first identifying and marking the target site with the patient positioned comfortably. To reduce the risk for complications, the operator should position the transducer probe so that the thickest portion of the target fluid collection is in the center of the screen. A separation of 10 mm between the visceral and parietal pleura is usually deemed adequate to tap safely.⁶⁵ Areas with the curtain sign representing intermittently appearing lung or with incursion of the diaphragm during respiration are relatively contraindicated. All intervening structures along the trajectory of the needle must be identified. If free air is present in the thorax due to hydropneumothorax, visualization is lost; in that case, ultrasonographic guidance must be limited to identifying the position of the diaphragm.⁴⁸ The depth of needle insertion can be estimated on the ultrasonography screen, but, because the probe compresses near-field soft tissues, this distance can be misjudged; the problem in estimating distance is exacerbated in edematous or obese patients.

The timing of the procedure can be concurrent with the ultrasonography (i.e., real-time) or at a later time. In a real-time procedure, the needle is usually directed at a downward angle of 45 degrees to the long-axis of the probe over the rib; the operator attempts to keep the entire length of the needle in view along its trajectory. Real-time thoracentesis requires a sterile probe sheath and an assistant to hold the probe during needle insertion. This unnecessarily complicates the procedure without any evidence of improving either safety or success.⁴⁸ If the site is marked for a thoracentesis that will be performed at a later time, the patient position must be kept constant to avoid a change in location of the pleural fluid. The patient is then cleaned, draped, and anesthetized, and the needle is placed at the same angle as the probe, usually perpendicular, at the target site. The point of entry is ideally superior to the rib to avoid injury to the neurovascular bundle. If catheters are inserted, ultrasonography can be used to confirm the position of catheters (Video 20-14). The pleural catheter will appear as

a hyperechoic linear structure within an anechoic fluid collection. Postprocedure ultrasonographic scans of the non-dependent chest wall to identify lung sliding and comet-tail artifacts exclude an iatrogenic pneumothorax.^{12,13}

Despite ultrasonographic guidance, taps can occasionally be unsuccessful. Reasons include plugging of the aspiration needle or the presence of loculations or septations preventing free drainage. Operator error due to compression artifacts may result in misjudging the depth of the effusion. The patient may have moved in the time between the scan and the tap. If a tap is dry, the thoracentesis needle should be withdrawn immediately and the patient rescanned. Repeat scanning enables repositioning of the entry point as well as exclusion of complications such as pneumothorax.

Ultrasonographic scanning can also assess the result of prior interventions. A successful pleurodesis resulting in pleural symphysis can be determined by the absence of lung sliding.⁶⁶ Successful resolution of pneumothorax by aspiration or chest tube drainage can be assessed by ultrasonography; in fact, ultrasonography can identify residual pneumothorax better than chest radiographs.⁶⁷

Ultrasonographic guidance can be used to guide the biopsy of peripheral lung lesions, pleural masses, and anterior mediastinal tumors. Closed pleural biopsies with an Abrams needle when guided by ultrasonography have been shown to contain pleura in 91% and be diagnostic for tuberculosis in 82% of cases.⁶⁸ Because it can distinguish solid from liquid components, ultrasonography is especially useful in avoiding necrotic areas. However, transthoracic needle biopsy of a lung or mediastinal lesion should only be performed by pulmonologists with expert knowledge of both ultrasonography and needle biopsy techniques,⁶⁹ because real-time needle visualization is necessary and the potential for complications is increased.

Prerequisites for ultrasonographically guided transthoracic needle biopsy are the presence of an acoustic window and the absence of overlying structures such as bone or aerated lung. Absolute contraindications include inability of patients to cooperate, to maintain an optimum position, or to control coughing. Uncorrected coagulopathy, thrombocytopenia (platelet count $< 50 \times 10^9/L$), uremia, and severe pulmonary hypertension are relative contraindications. Bronchiectatic and chronic cavitory lesions are considered poor candidates for biopsy because of the limited capacity for local tamponade of any bleeding.⁶⁹

The preferred method of biopsy is by the coaxial technique, in which a stylet with an introducer is inserted and biopsies are taken through the introducer when the stylet is removed. Patients are asked to hold their breath when the needle is advanced, during biopsy, and whenever the introducer is not occluded by the stylet. The needle should be visualized throughout its path, and failure to do so is usually the result of poor angulation. Any undue resistance should raise the suspicion of poor placement. Needle aspirates yield cytologic material; core biopsies for a tissue diagnosis are needed if tumors such as mesothelioma, lymphoma, teratoma, or thymoma are suspected. Core biopsies are also preferred for lung cancer tumor markers such as epidermal growth factor receptor mutation analysis.

Complications of biopsy include pneumothorax, hemoptysis, air embolism, and perforation of other organs. The

pneumothorax rate in needle biopsy of lung lesions has been reported in less than 4%,⁷⁰⁻⁷³ a low rate probably because most of the biopsied lesions were abutting the pleura. Air embolism can result when a swing in intrathoracic pressure draws air into the pulmonary veins via the introducer.

DOCUMENTATION⁷⁴

Appropriate documentation of ultrasonographic findings and interventional procedures is essential for research, reimbursement, and communicating medical information. Capturing of images or video clips enables comparisons with future scans and assessment of a patient's progress. Standard documentation should include patient identification, time and date of procedure, operator identification, patient position, transducer type and location, and indications and anatomic extent of the study. Reports should comment on normal findings, pathologic conditions, subjective measures of certainty (probable versus possible), and changes compared with previous scans. Reports on pleural effusions should mention location, echogenicity, degree of homogeneity, and estimated size. A comment should also be made on the pleural surface characteristics and the presence of any nodules or septations if applicable. Any limitations of the study should also be noted. If interventional procedures were performed, documentation usually includes the site, anesthesia, specimens obtained, complications, and follow-up instructions.

TRAINING

The American College of Chest Physicians and La Société de Réanimation de Langue Française have listed the competencies required for lung and pleural ultrasonography⁷ (see Table 20-3). The European Society of Intensive Care Medicine has agreed to use this as a foundation document in determining training standards.³ The basic principles necessary before acquiring these specific competencies include knowledge of ultrasound physics, machine settings, and manipulation of the probe to acquire adequate images. An understanding of ultrasonographic anatomy and image interpretation is also necessary.⁷ For patient safety, self-awareness is needed of the limitations of capability when embracing new technology. Pulmonologists need to identify poor-quality or complex images that require further consultation with experienced colleagues or referral to a radiologist. In addition, when scans do not correlate with clinical findings, the scans should not be acted upon until either expert opinion is sought or an alternative imaging method such as CT is obtained.

Current recommendations for general critical care ultrasonography require a theoretical program with image-based learning before moving to proctored procedures.³ Hands-on training on normal volunteers facilitates teaching of probe manipulation, spatial orientation, and normal anatomy. This helps perfect psychomotor skills and the proper use of buttons on the ultrasonography machine. For proctored procedures on patients, a logbook is recommended in which trainees should write detailed

interpretation reports for verification by trainers.³ There is no consensus on the number of procedures required for credentialing. However, based on echocardiography and emergency medicine standards, proctored examinations in 25 to 30 cases for each single application is a reasonable target to achieve competence in image acquisition.^{3,75,76}

ADVANTAGES AND DISADVANTAGES

The advantages of ultrasonographic imaging include bedside availability and the relative ease of performing repeated examinations. Imaging is real-time and free of harmful radiation. There are no documented side effects, and discomfort is minimal. Ultrasonography also provides excellent delineation of solid and liquid tissue structures. Furthermore, this modality is easily mastered once the image acquisition, interpretation, and the technical jargon (see Table 20-1) are learned. Despite the absence of randomized controlled trials, ultrasonographically guided interventional procedures in the thorax are likely to improve diagnostic yield and reduce complications by providing visual guidance.⁷⁷ Bedside ultrasonography enables clinicians who understand the clinical context of patients to perform the most appropriate scans directed to address clinically relevant questions.

The disadvantages of ultrasonography are primarily related to the fact that it is heavily operator dependent. Retrospective review of images provides only limited quality control. There is no scout scan to give a global picture for orientation. In addition, the basic ultrasonographic evaluation cannot determine the exact position of devices such as the endotracheal tube, central lines, and feeding tubes in the body. Image quality is degraded in patients who are edematous, muscular, or obese. Chest wounds or dressings prevent optimal probe placement, and subcutaneous emphysema can reflect so much signal that imaging is not possible. The bedside nature of ultrasonography raises issues of infection control. Portable machines should never be placed on patients' beds and should ideally have independent stands. Sterile sheaths should be employed in all real-time interventional procedures together with standard aseptic techniques. Ultrasonography gel can be a culture medium for bacteria,⁷⁸ and it is common courtesy to clean off all gel from the patient's body at the end of the procedure. The ultrasonography machine should also be wiped clean between studies with special attention given to components that may contribute to nosocomial transmission of infection: the transducer probe, cable, and keyboard.

Key Points

- Ultrasonography offers the advantages of real-time, bedside, radiation-free imaging that extends the possibilities for diagnosis and treatment by pulmonary and critical care physicians.
- The choice of transducer probes depends on frequency (compromising between spatial resolution and depth

of scan) and footprint (determining acoustic window size).

- Patient and probe position must be considered when assessing gravitationally dependent pathologic conditions such as pneumothorax and pleural effusion.
- Anatomic structures are identified based on their location and echogenicity.
- Ultrasonographic guidance for thoracentesis and pleural catheter placement increases the success of these procedures and reduces complications.
- A key disadvantage of ultrasonography is that it is operator dependent, thereby limiting retrospective analysis of previously acquired images.

INTRODUCTION

Positron emission tomography (PET) with ^{18}F -fluorodeoxyglucose (FDG) is a noninvasive imaging technique with several important applications in respiratory medicine. PET has long been used to evaluate inflammatory conditions such as sarcoidosis or idiopathic pulmonary fibrosis; for example, in small series of about 20 patients, the extent and/or activity of these diseases could be assessed more precisely by PET/computed tomography (CT) than by ^{67}Ga single-photon emission computed tomography scintigraphy.¹⁻³ PET has also been studied in patients with posttransplantation lymphoproliferative disease, in which a possible role in staging and follow-up was suggested.^{4,5}

The vast majority of data and clinical applications of PET, however, pertain to patients with respiratory malignancies, such as lung cancer or mesothelioma, and these are the main subjects of discussion in this chapter. Because FDG is by far the most commonly used tracer for this purpose, the term *PET* refers to FDG-PET unless stated otherwise.

PRINCIPLES

PET CAMERA

A PET camera produces three-dimensional images that represent the distribution of radioactivity within the body of a patient. Any molecule labeled with a positron-emitting radioisotope can be used to generate PET images. The PET camera consists of a full ring of several thousand scintillation detectors to generate the image, resulting in higher sensitivity to radioactivity and better spatial resolution than the conventional gamma camera. The spatial resolution of contemporary PET cameras is around 4 mm, allowing accurate characterization of lesions larger than 8 mm.

Modern PET cameras are hybrid systems in which a PET camera is combined with either a CT⁶ or magnetic resonance camera. Hybrid PET/CT cameras are now considered standard, whereas PET/magnetic resonance is an emerging technology. Compared to PET alone, hybrid PET/CT cameras provide three main advantages: (1) CT-based *attenuation*

correction (AC) is applied to the PET image to correct for absorption by the body of the patient; (2) there is increased accuracy of the exact position of the lesion and morphologic characterization of the underlying correlate, reducing equivocal findings; and (3) the combined image increases the confidence of the reporting physician.

Typical scan times for modern PET/CT are in the order of 15 minutes for a skull-to-thigh, “whole body,” image. Unless a separate dedicated contrast-enhanced CT scan is already available, PET/CT is preferably combined with high-dose, contrast-enhanced diagnostic CT than with low-dose CT; with high-dose CT, the PET/CT is more precise for *tumor-node-metastasis* (TNM) staging because of better AC and localization.⁷ It has been demonstrated that the use of oral or intravenous contrast agents does not induce clinically significant changes in the PET images.⁸

METABOLIC TRACER: FDG

For clinical cancer imaging the glucose analogue FDG is by far the most common tracer. Its use is based on the increased cellular uptake of glucose, due to both an increased expression of glucose transporter proteins and a much higher rate of glycolysis of cancer cells.⁹ FDG, a glucose analogue in which the oxygen molecule in position 2 is replaced by a positron-emitting fluorine-18 atom, undergoes the same uptake as glucose but is metabolically trapped and sequestered in neoplastic cells after phosphorylation by hexokinase.¹⁰ The radiation dose for a typical examination is in the order of 5 to 8 mSv,¹¹ comparable to the effective dose of a diagnostic chest CT (7 to 7.5 mSv). The FDG uptake is generally expressed as the *standardized uptake value* (SUV), a semiquantitative measure of FDG-uptake that expresses the uptake of a lesion as a function of the total injected dose.

INTERPRETATION OF PET IMAGES

For diagnosis and staging, visual analysis relies on the detection of foci with activity higher than background not caused by physiologic processes, both for the discrimination of nodules and for the evaluation of mediastinal involvement. Non-AC images should be examined to detect

small lung lesions, because non-AC images have better contrast for such nodules than AC images.¹² High physiologic FDG uptake is present in the brain, kidney, and urinary tract (urinary excretion) and can be present in the heart.¹³ The high uptake in the brain interferes with lesion detection. There is a low degree of physiologic uptake of FDG in the other intrathoracic structures.

False-positive findings are possible, because FDG uptake is not tumor specific and can be found in all active tissues with high glucose metabolism, particularly in sites of inflammation. Therefore FDG-positive findings, especially if isolated and decisive for patient management, require confirmation. The differentiation between metastasis, a benign or inflammatory lesion, and even an unrelated second malignancy should be established by other tests or tissue biopsy.¹⁴ The major causes of false-positive results in chest pathologic conditions are infectious, inflammatory, and granulomatous disorders (Table 21-1)¹⁵ and recent medical procedures.^{16,17}

False-negative findings are less common and may be due to lesion-dependent or technical factors (see Table 21-1). A critical mass of metabolically active malignant cells is

required for PET detection. Therefore careful interpretation is warranted in tumors with low FDG uptake, such as small-sized very well differentiated adenocarcinoma, adenocarcinoma with lepidic growth, or carcinoid tumors. In addition, even in tumors with high FDG uptake, lesions less than 8 mm may prove falsely negative due to the limitations in spatial resolution; in the lower lung fields, due to the greater respiratory motion there, the detection limit may even be 10 mm.¹⁸ One interfering factor inherent to the technique is a high blood glucose level, which should be checked and be within an acceptable range (typically 60 to 180 mg/dL) before tracer injection.

DIAGNOSIS

Noncalcified *solitary pulmonary nodules* (SPNs) are common findings on chest radiograph or CT examination in clinical practice and have become even more frequent with the recent interest in low-dose chest CT for early lung cancer detection.¹⁹ Initially, PET studies in the diagnosis of SPNs used a threshold *maximum SUV* (SUV_{max}) above 2.5 for the diagnosis of malignancy. Applying this criterion, overall sensitivity, specificity, and positive and negative predictive values of 96%, 78%, 91%, and 92%, respectively, were reported in a meta-analysis based on series with nodules larger than 1 cm²⁰ (Fig. 21-1).

However, more recently the use of an SUV_{max} level below 2.5 to exclude malignancy has been challenged as too restrictive.²¹ It is true that solid malignant lesions of at least 1 cm will usually have an SUV_{max} above 2.5, but smaller cancers, lesions with ground-glass appearance on CT (e.g., the lepidic type of adenocarcinoma^{22,23}) (Fig. 21-2), or tumors with low metabolism (e.g., carcinoid tumors^{24,25}) may have an SUV_{max} below 2.5. In a large prospective study of PET/CT scans of indeterminate lesions, SPNs smaller than 2.5 cm were found to have a 24% chance of being malignant when the SUV_{max} was between 0 and 2.5, 80% if between 2.6 and 4.0, and 96% if 4.1 or more.²⁶

Rather than using a fixed SUV_{max} criterion as a threshold, the visual information from PET images—lesions with any increased FDG uptake being potentially malignant—should be added to a comprehensive nodule assessment based on clinical characteristics such as smoking and age, CT imaging characteristics such as appearance (ground glass, semi-solid, or solid) and margins, and growth pattern if available. Using this approach, the chance of identifying an SPN as malignant is improved compared with just using the information from PET alone. The benefit of PET in this setting was confirmed in a series of 106 radiologically indeterminate SPNs, of which 61 were malignant²⁷; PET improved the accuracy over a prediction model that did not incorporate PET data²⁸ by 13.6%.

STAGING

TNM STAGING

The TNM staging system classifies malignant tumors according to the extent of the primary *tumor* (T), the spread to locoregional *lymph nodes* (N), and the presence of distant

Table 21-1 Causes of False-Negative and False-Positive Findings on PET Scanning

FALSE-NEGATIVE FINDINGS

- Lesion dependent
 - Small tumors (<8-10 mm)
 - Ground-glass opacity neoplasms (adenocarcinoma with lepidic pattern)
 - Carcinoid tumors
- Technique dependent
 - Hyperglycemia
 - Paravenous FDG injection
 - Excessive time between injection and scanning

FALSE-POSITIVE FINDINGS

- Infectious-inflammatory lesions
 - (Postobstructive) pneumonia—abscess
 - Mycobacterial or fungal infection
 - Granulomatous disorders (sarcoidosis, granulomatosis with polyangiitis [Wegener granulomatosis])
 - Chronic nonspecific lymphadenitis (Rheumatoid) arthritis
 - Occupational exposure (anthracosis/silicosis)
 - Bronchiectasis
 - Organizing pneumonia
 - Reflux esophagitis
- Iatrogenic causes
 - FDG embolus
 - Invasive procedure (puncture, biopsy)
 - Talc pleurodesis
 - Radiation esophagitis and pneumonitis
 - Bone marrow expansion after chemotherapy
 - Colony-stimulating factors
 - Thymic hyperplasia after chemotherapy
- Benign mass lesions
 - Salivary gland adenoma (Warthin)
 - Thyroid adenoma
 - Adrenal adenoma
 - Colorectal dysplastic polyps
- Focal physiologic FDG uptake
 - Gastrointestinal tract
 - Muscle activity
 - Brown fat
 - Unilateral vocal cord activity
 - Atherosclerotic plaques

Figure 21-1 Two 60-year-old men with solitary pulmonary nodules differentiated by PET/CT. The first patient (A–E) presented with a 19-mm smooth nodule (arrows, B and E) in the left upper lobe on CT (B), with limited growth over a 4-month period. Both the coronal, attenuation-corrected (A) and non-attenuation-corrected transverse (C and D) PET images show no increased ^{18}F -fluorodeoxyglucose (FDG) uptake within the nodule, with a maximum standardized uptake value (SUV_{max}) of 2.1. The fusion image (E) shows uptake in the lesion lower than in the mediastinal vessels. Histologic analysis following wedge resection demonstrated a pulmonary fibrous hamartoma. The second patient (F–J) presented with a more irregular 15-mm nodule (arrows) in the right upper lobe. There is intense focal uptake in the right lung on the maximum-intensity projection image (J) and on both the attenuation-corrected (G) and non-attenuation corrected (H) transverse images, corresponding to the site of the nodule (I). The SUV_{max} was 6.4, and the lobectomy specimen showed moderately to poorly differentiated pulmonary adenocarcinoma.

metastasis (M); as a result, lung cancer patients of different TNM subsets with similar prognoses can be grouped into stages. Stage is the most important factor in prognosis and choice of treatment,²⁹ which means that reliable noninvasive methods for accurate staging are extremely important. CT scans, endoscopic techniques, and surgical staging procedures are key factors, but the addition of PET to these conventional methods has been shown to improve the staging process substantially; PET greatly aids in distinguishing patients who are candidates for therapy with curative intent, such as surgical resection or intense multimodality treatment, from those who are not.³⁰

The T Factor

Modern multislice CT images allow detailed evaluation of the anatomic relationships among the tumor and the lung fissures, which may determine the type of resection, and among the tumor and both the mediastinal structures and the pleura and chest wall. In addition, integrated PET/CT images may enhance precise definition of chest wall and mediastinal infiltration or correct differentiation between tumor and peritumoral inflammation or atelectasis^{31–33} (Fig. 21-3).

The N Factor

It has been clear since the initial studies^{34,35} that the addition of PET to CT results in more accurate lymph node

staging than CT alone, with an overall sensitivity of 80% to 90% and a specificity of 85% to 95% for the detection of pathologic nodes.^{36–38} In addition, the absence of mediastinal lymph node disease on PET/CT has a high negative predictive value, so that invasive lymph node staging tests can often be omitted, allowing these patients to proceed straight to surgical resection. However, there are limitations to relying on negative PET results; one should have less confidence in negative PET results in cases of a primary tumor larger than 3 cm, insufficient FDG uptake in the primary tumor, a centrally located tumor, or concurrent hilar nodal disease that may obscure coexisting N2-disease on PET. On the other hand, positive PET/CT findings determine the location of suspect lymph nodes and thereby help to direct tissue-sampling procedures, such as endobronchial ultrasonographically-guided transbronchial needle aspiration or cervical mediastinoscopy. Because of false-positive images in lymph nodes—based on the conditions listed in Table 21-1—proof of lymph node involvement in pathologic processes should be sought in most patients with positive mediastinal nodes on PET, except those with obvious bulky nodes on imaging.

The M Factor

PET added to CT is almost uniformly superior to CT alone, except for brain imaging, where the sensitivity for detecting lesions is unacceptably low due to the high glucose uptake

Figure 21-2 False-negative ^{18}F -FDG-PET finding. Axial chest CT displayed in soft tissue (A) and lung (B) windows in a 69-year-old man shows a pulmonary ground-glass opacity persisting for 1 year (arrow). There is no increased FDG uptake on the attenuation-corrected images (C), and the lesion has low FDG uptake comparable to the surrounding lung tissue on the fusion images (arrow, D). The maximum standardized uptake value was 1.5. Histologic analysis demonstrated pulmonary adenocarcinoma with lepidic growth pattern.

of normal surrounding brain tissue. For detecting extrathoracic metastases, the pooled sensitivity and specificity for PET/CT were 77% (95% confidence interval [CI], 47% to 93%) and 95% (95% CI, 92% to 97%), respectively, in a recent meta-analysis.³⁹ CT and especially magnetic resonance imaging remain the methods of choice for brain imaging.

For bone metastases, PET is more accurate than $^{99\text{m}}\text{Tc}$ methylene diphosphate bone scanning: sensitivity is at least as good (90% to 95%) and specificity is far better (95% versus 60% for bone scan).^{40,41} Limitations are that PET only images from the head to just below the pelvis and thus will miss lesions outside this range and that PET may not detect osteoblastic lesions, which nonetheless are rare in untreated lung cancer. For adrenal gland metastases, PET has a high sensitivity, so that an equivocal lesion on CT without FDG uptake will usually not be metastatic. PET can also be of help in differentiating hepatic lesions that remain indeterminate by conventional studies. PET may also reveal metastases in sites that escape attention in conventional staging (Fig. 21-4), including soft tissue lesions, retroperitoneal lymph nodes, barely palpable supraclavicular nodes, and painless bone lesions. Exclusion of malignancy requires caution when smaller lesions (<1 cm) are present (see Table 21-1). A particular example is a small contralateral lung nodule—a common finding in the era of chest multislice CT imaging—where negative PET/CT results often do not guarantee certainty, so that invasive sampling (e.g., thoracoscopy) is still needed to exclude malignancy.

PET/CT has long been used to assess pleural involvement, initially with promising results,^{42,43} but recently with more variable results.⁴⁴ Small pleural deposits can be missed on PET/CT, because of their low tumor load and/or partial

volume effects, whereas false-positive findings may be caused by inflammatory pleural lesions. If the diagnosis of pleural abnormalities will determine the chance for treatment with curative intent, verification of a pathologic process with cytologic analysis or thoracoscopy is often needed.

INFLUENCE ON TREATMENT CHOICES AND PLANNING WITH CURATIVE INTENT

PET has a significant complementary role to CT for two reasons. First, PET can detect unexpected lymph node involvement or distant organ metastatic spread (see Fig. 21-4). After a negative conventional staging, previously unknown metastases are found on PET/CT in 5% to 20% of patients, in increasing numbers from clinical stages I–III tumors.^{45–54} Second, PET is able to determine the nature of some lesions that are equivocal on conventional imaging.^{45–47,49} There is no problem of interpretation when whole-body PET shows metastases in many sites, but an isolated suspect lesion that determines radical treatment intent should always be verified by other tests or tissue sampling, because of the risk for a false-positive finding (see Table 21-1) or a second primary tumor. In one large retrospective series, solitary extrathoracic lesions were documented in about 20% of the patients; about half of these were metastatic, whereas the other half were either unrelated to lung cancer (inflammatory or other benign lesions) or second primary tumors.⁵⁵

The effect of adding PET or PET/CT to a standard staging algorithm has been investigated in several randomized controlled trials. Two earlier trials looked at the advantages of stand-alone PET and reported seemingly contradictory

Figure 21-3 Use of ^{18}F -FDG-PET/CT to determine tumor stage. A 76-year-old woman presented with a large tumor mass in the left upper lobe that showed intense FDG uptake (A). On both the transverse (B) and sagittal (E) CT images the consolidation extends to the chest wall. The corresponding PET images show intense uptake in the viable rim, with central photopenia in the necrotic part of the tumor (C and F). The fusion images demonstrate that the metabolically active tumor component does not reach the chest wall (D and G) and is surrounded by postobstructive atelectasis.

results, perhaps because of differences in trial design. In the Dutch trial,⁵⁶ which found value in adding PET to the standard workup, the end point—“futile thoracotomy”—was clearly defined as indicating benign disease, explorative thoracotomy, pathologic stage IIIA-N2/IIIB, or postoperative relapse or death within 12 months. In contrast, in the Australian study,⁵⁷ which found less value in adding PET, there were no benign lesions, surgery was considered to be of use in some stage IIIA-N2 patients, and no strict follow-up terms were predefined. The Australian trial also focused on clinical stage I and II patients only, from which less additional benefit of PET was expected based on previous non-randomized accuracy studies.

Three later trials used PET/CT imaging in addition to standard workup, two of which took place in the surgical setting (Table 21-2). The study of Fischer et al⁵⁸ largely reproduced the Dutch experience, in which addition of PET led to a significant reduction of futile thoracotomies. The study of Maziak et al⁵⁹ mainly looked at improved correct upstaging in resectable stages I–III *non-small cell lung cancer* (NSCLC) and met this primary end point. Overall, in the two studies there was a 4% to 11% increased detection rate of stage IV disease,^{58,59} and the use of PET/CT led to a change in patient management, both in intent (curative versus pal-

liative) and modality (chemotherapy versus other modalities). In a study of unresectable stage III NSCLC, 21/140 (15%) patients were correctly upstaged with PET/CT versus 4/149 (2.7%) with CT alone.⁶⁰ Thus the overall evidence points to significantly more accurate TNM staging with PET/CT than with conventional imaging alone. This leads to true benefits, such as stage migration,⁶¹ better treatment choices, and perhaps better outcome,⁶² although the latter still needs to be proven, because randomized controlled trials have been underpowered to assess this end point.

It has been shown in many radiotherapy planning studies that PET/CT influences the accurate delineation of target volumes for radiotherapy. In general the PET-based volume delineations are smaller than those with CT alone, mainly due to more accurate nodal staging⁶³; the lower tumor volume permitted radiation dose escalation to the tumor in a substantial number of patients. Prospective clinical trials using selective nodal irradiation based on PET/CT scanning reported isolated nodal failures in fewer than 5% of patients treated with chemoradiotherapy,^{64,65} which is lower than the 13% rate of false-negative PET results reported in CT-positive lymph nodes.⁶⁶ The lower recurrence rate than expected might be explained by the incidental irradiation of lymph nodes adjacent to the planning target volume. In

Figure 21-4 Detection of distant metastasis (M1b) outside the traditional scanning range of CT for lung cancer staging. ^{18}F FDG-PET/CT was performed in a 54-year-old man with a primary pulmonary adenocarcinoma. The maximum-intensity projection image shows two sites with intense pathologic uptake (**A**, arrows). Note intense uptake at the primary tumor with central photopenia (**B–D**) due to necrosis (maximum standardized uptake value [SUV_{max}] 13.7). In addition, there is strong focal uptake (**E–G**) in the left ischiorectal fossa (SUV_{max} 8.4). This lesion would have been undetected with the conventional approach of performing CT through the chest and upper abdomen for lung cancer staging. A biopsy of the lesion was performed under ultrasonographic guidance, and the lesion was found to represent metastasis from the lung adenocarcinoma.

Table 21-2 Randomized Controlled Studies Comparing Conventional Staging to Integrated PET/CT Staging in Patients with NSCLC

Study and year	N	Population	Proportion Stages I–II	Primary Outcome
Fischer et al ⁵⁸ 2009	189	Stages I–III	33%	Futile thoracotomy 52% vs. 35% ($P = 0.05$)
Maziak et al ⁵⁹ 2009	337	Stages I–IIIA	90%	Correct upstaging 6.8% vs. 13.8% ($P = 0.046$)
Ung et al ⁶⁰ 2009	304	Stage III	0%	Correct upstaging 2.7% vs. 15% ($P = 0.002$)

N, number of patients; NSCLC, non-small cell lung cancer.

addition, PET/CT-based delineation might be crucial to avoid geographic misses leading to treatment failures. Because of the possibility of false-positive lymph nodes on PET, invasive nodal staging using endosonography (endobronchial ultrasonography or endoscopic ultrasonography) or mediastinoscopy may be warranted if the nodes concerned would have a major impact on defining the radiation treatment field (see Chapter 22).

PET-based delineation of the primary tumor usually does not add significantly to that of CT-based delineation, except in situations with postobstructive atelectasis. The optimal method of delineation still remains to be defined. An automated PET/CT delineation may reduce the interobserver variability in treatment planning compared to CT alone.⁶⁷ PET may also identify high FDG-uptake regions within the primary tumor as being more radioresistant.⁶⁸ Work is in progress to plan higher radiation doses to these potentially radioresistant areas. Radiation dose escalation using an integrated boost to high FDG-uptake regions within the

primary tumor proved to be safe and feasible in a small randomized phase II study.⁶⁹

PROGNOSIS

Several PET staging studies have clearly demonstrated TNM stage migration. The possible effect of stage migration may in part account for an apparent improvement in survival of treated patients in both early and advanced disease stage cohorts. The artifactual improvement seen with stage migration is widely referred to as the “Will Rogers phenomenon,” in which patients that move from one stage to another can improve the apparent survival in both stages.^{61,70} (Will Rogers, the American comedian, observed: “When the Okies left Oklahoma and moved to California, they raised the average intelligence level in both states.”) As mentioned earlier, the randomized controlled trials to date have been underpowered to evaluate the potential individual patient survival benefit due to TNM stage migration brought about by PET.

PET has also been shown to predict the prognosis of patients with NSCLC.⁷¹ In a recent systematic review and meta-analysis, the SUV of the primary tumor at diagnosis was found to predict outcome in NSCLC, especially in the earlier stages.⁷² These studies almost uniformly found a better overall survival among patients with a metabolic activity lower than the threshold SUV value, calculated from either the most discriminative log-rank SUV value or the median SUV. However, although SUV may be a way to assess prognosis, there is no true cutoff point suitable for broad clinical use. Instead of a true cutoff point, there may rather be a continuous SUV spectrum of a gradually worsening prognosis. When baseline SUV was incorporated as a continuous variable in a Cox proportional hazards model, a one-unit increase in SUV was associated with a 7% increase in hazard of death in resected stages I–III NSCLC⁷³ and a 6% increase in hazard of death in inoperable NSCLC patients treated with radiotherapy.⁷⁴

HEALTH ECONOMICS

As respiratory oncologists, we aim for the best-quality health care for our patients but acknowledge the need for financial prudence. The major cost of modern oncology practice, however, does not lie in the baseline diagnostic process, but in the delivery of expensive treatments and the morbidity related to possible side effects. Therefore application of economic modeling to the use of PET has to be based on both diagnostic and therapeutic aspects of health care expenditure within a daily clinical setting.

In a recent overview of all economic evaluations of PET in oncology performed between 2005 and 2010, it was concluded that the strongest evidence for cost-effective use of PET was for the staging of NSCLC, where there may be benefits both for patients in terms of a possible increase in life expectancy and for the health care system in terms of cost savings resulting from the number of invasive procedures avoided.⁷⁵ Taking into account the superior accuracy of PET/CT compared to PET alone in lung cancer staging, the health economic impact in terms of cost-effectiveness can most probably be extended to PET/CT. Since the

introduction of PET/CT technology into clinical medicine in 2001, additional studies in respiratory oncology have confirmed the cost-effectiveness of this integrated scanning method.^{76,77} Furthermore, PET has been shown to be cost-effective for characterizing SPNs and to be the most cost-effective diagnostic strategy for nodules of low to moderate pretest probability of malignancy on CT.⁷⁸

LESS CLASSIC INDICATIONS

SMALL CELL LUNG CANCER

Small cell lung cancer (SCLC) typically shows very high FDG accumulation; however, the value of PET for SCLC is not as well established as for NSCLC. For management of SCLC, the data on the use of PET are less robust than for NSCLC, because the emphasis on systemic and radiation therapy as opposed to surgical resection provides less histologic data to serve as the gold standard. Furthermore, most studies were rather small (mean $n = 40$) and retrospective in nature. A review of 14 studies comparing FDG-PET with conventional staging procedures found an overall cumulative staging concordance between PET and conventional imaging in 84%.⁷⁹ Based on PET, limited stage SCLC was upstaged to extensive stage SCLC in 18% of patients, and extensive stage SCLC was downstaged to limited stage in 11%. The information on PET might result in considerable changes in patient management, ranging from 27%⁸⁰ to 47%⁸¹ across studies. The use of PET/CT resulted in changes to the three-dimensional conformal radiation therapy plan in 58% of patients, mainly by decreasing the target volume (in the setting of atelectasis) or detecting unsuspected nodal or pulmonary foci.⁸² For prognostic predictions, pretreatment PET values had no value for stages I–III SCLC, but a complete metabolic response on posttreatment PET/CT was associated with better outcome in retrospective analyses.^{83,84}

MESOTHELIOMA

Integrated PET/CT imaging is playing an increasing role in the assessment of suspected or known *malignant pleural mesothelioma* (MPM, Fig. 21-5). PET/CT could be an effective tool in the correct differentiation of malignant (mainly MPM) and benign pleural diseases in asbestos-related CT findings, with an overall accuracy of higher than 90% and a negative predictive value of above 90%.^{85,86} Compared to CT alone, PET/CT is significantly more accurate in baseline TNM staging of patients who are considered appropriate candidates for multimodal therapy.⁸⁷⁻⁸⁹ Although PET/CT does not provide additional information about the primary tumor compared to CT alone, it identifies a higher number of metastatic mediastinal lymph nodes and/or unknown distant metastatic disease in up to two thirds of patients, with a significant clinical impact on treatment planning. Early evidence also suggests that PET/CT may have a role in evaluating response to therapy in MPM,⁹⁰ which is interesting because the assessment of response in patients with MPM according to standard response criteria on CT is far from simple. More work to define response criteria for MPM on PET is needed. Furthermore, a prospective study in

Figure 21-5 ^{18}F -FDG-PET/CT in mesothelioma. A 67-year-old patient underwent FDG-PET/CT for staging of a primary epithelioid pleural mesothelioma. The maximum-intensity projection images (**A**) show diffuse, intense uptake corresponding to the right pleural surface. Coronal (**B** and **C**) PET images show linear intense uptake involving a large portion of the lateral and medial pleura, with a small area on the lateral side without increased uptake. Transverse PET images show increased uptake involving nearly 330 degrees of the pleural circumference (**D** and **G**), corresponding to the neoplastic irregular thickening of the pleura on the corresponding CT images (**E** and **F**).

patients with nonsarcomatoid MPM observed that baseline total glycolytic volume on PET was more predictive of survival than CT-assessed TNM stage in a multivariate analysis.⁹¹ These observations of prognostic capability still require prospective validation.

NEUROENDOCRINE TUMORS

Neuroendocrine tumors (NETs) arise in cells of the amine precursor uptake and decarboxylation system. NETs of the lung are divided in four categories: typical carcinoid,

atypical carcinoid, large cell neuroendocrine carcinoma, and small cell neuroendocrine carcinoma.⁹² FDG uptake is often low in typical carcinoid—a well-known cause of potentially false-negative results—whereas in higher-grade NETs the FDG uptake can be similar to that of NSCLC and SCLC.⁹³ Alternative tracers have been studied for detection and staging of NET with low FDG avidity. Neuroendocrine cells synthesize and secrete a range of peptide hormones. The molecular features of this hormone production have been harnessed to provide imaging targets. The most studied target is the *somatostatin receptor* (SSTR), a

seven-transmembrane G-coupled peptide receptor, which plays a role in the control of hormone secretion and cell growth⁹⁴ and is internalized upon ligand binding.⁹⁵

Synthetic peptides derived from the somatostatin hormone have been coupled with chelators and radiolabeled with a range of different radionuclides, of which the most interesting for PET are the so-called ⁶⁸Ga-DOTA-peptides labeled with the generator-derived gallium-68. These tracers consist of a vector molecule binding the SSTR (e.g., TOC, TATE, NOC), a chelator (DOTA), and a positron-emitting radionuclide (gallium-68). Three of these tracers are currently in clinical use: ⁶⁸Ga-DOTATOC, ⁶⁸Ga-DOTATATE, and ⁶⁸Ga-DOTANOC, all with a high affinity for subtype 2 of the SSTR (low nanomolar range), varying affinity for subtypes 3 and 5, and low affinity for subtypes 1 and 4.⁹⁶ There have been many studies documenting the increased diagnostic performance of these ligands for detection of NETs.^{97,98}

A recent study documented expression of SSTR2A, the prime target for these radioligands, in more than 80% of patients with bronchial carcinoid, with expression by immunohistochemistry similar for typical and atypical carcinoid.⁹⁹ This results in very high uptake rates in typical and atypical bronchial carcinoid, with median SUV_{max} around 15, 20, and 25 for ⁶⁸Ga-DOTATATE,⁹³ ⁶⁸Ga-DOTATOC,¹⁰⁰ and ⁶⁸Ga-DOTANOC,¹⁰¹ respectively (Fig. 21-6). In most cases, bronchial NETs will show an uptake either of an SSTR ligand or of FDG, with virtually no tumors showing uptake of both or neither tracer⁹³; typical carcinoids show

more avidity for the SSTR ligand, whereas atypical carcinoids and higher-grade lesions show more avidity for FDG.^{101a} Comparing FDG and ⁶⁸Ga-DOTATATE uptake, an interesting observation has been made regarding central bronchial carcinoids,¹⁰² which often present with postobstructive atelectasis. ⁶⁸Ga-DOTATATE consistently showed low uptake in these tumors, whereas FDG showed moderate to very high uptake because of postobstructive inflammation or infection with low uptake in the primary tumor.⁹³

RESPONSE TO THERAPY

FDG uptake in tumors is related to (1) the number of viable cancer cells, (2) their metabolic activity and proliferation capacity, and (3) the presence of inflammatory cells.¹⁰³ In many clinical settings the metabolic changes caused by cancer therapy precede the morphologic changes. This discrimination of viable tumor from nonviable tumor is the basis for the use of PET for the determination of response to therapy. Whenever PET scans are to be compared at different time points, it is crucial to perform each PET procedure according to a similar methodology, by standardizing the interval from last therapy, patient preparation, camera setting, reconstruction parameters, and image analysis.^{104,105}

For *early stage* NSCLC treated with *stereotactic ablative radiotherapy* (SABR), the prediction of outcome and assessment of response has become very important.¹⁰⁶ For the prediction of response to SABR, retrospective data

Figure 21-6 ⁶⁸Ga-DOTATATE PET in a patient with typical carcinoid. A 45-year-old woman with a history of a left lower lobectomy for a typical bronchial carcinoid underwent ⁶⁸Ga-DOTATATE PET/CT for a rising serum chromogranin level. The maximum-intensity projection images (A) show physiologic uptake in the pituitary gland, liver, and adrenal gland as well as particularly intense uptake in the spleen, kidneys, and bladder. There are three foci of intense pathologic uptake in the mediastinum (arrow, A). The transverse sections show increased tracer uptake in the left tracheobronchial angle and periesophageal lymph nodes (arrows, B–G) and nodes posterior to the left main bronchus (arrowheads, E and G). After a thorough surgical mediastinal lymph node dissection, these three nodes were confirmed as the only nodes with metastases from her typical carcinoid.

Figure 21-7 ^{18}F -FDG-PET/CT before and after induction chemotherapy. Patient with right upper lobe large cell carcinoma (arrow) with right hilar and right paratracheal adenopathy (arrowhead) (A, coronal PET image; B, C, CT scan; D, E, fusion images). After induction chemotherapy, a major decrease in the metabolic activity of the primary tumor and absence of FDG uptake in the mediastinum is noted (F–J). Surgical findings after induction chemotherapy indicated pT1N0.

regarding the value of pretreatment FDG uptake are too conflicting to be used in clinical practice.^{107,108} On the other hand, the assessment of response using a quantitative FDG uptake on PET at 3, 6, and 9 months after SABR for stage I NSCLC has been more promising. A systematic literature review suggests that changes on CT commonly seen following SABR are unlikely to be recurrence if the SUV_{max} is below 5 (i.e., a negative predictive value of 100%).¹⁰⁹ Further studies are needed, however, to validate these findings.

For *potentially resectable stage III NSCLC*, the evaluation of eligibility for resection after induction chemoradiotherapy is crucial, and restaging after induction therapy has been addressed in several studies (eTable 21-1). When mediastinal lymph nodes are restaged, integrated PET/CT has a sensitivity of up to 70% with a specificity of up to 90%. Mediastinal restaging with PET/CT thus reaches an accuracy level of some clinical value, but tissue confirmation is still mandatory to certify the real nodal status. New positive lesions, especially lymph nodes, need to be interpreted carefully because these new findings have a high false-positive rate.¹¹⁰ The findings on prediction of outcome in this setting are even more interesting. The classic prognostic parameters for surgery in these patients are obtained from the resected specimen(s) that demonstrate (1) downstaging of

mediastinal nodes and (2) the pathologic response in the primary tumor. These parameters are poorly predicted by the clinical or CT-graphic evolution during therapy. However, in prospective studies, both the residual FDG uptake in the primary tumor after induction and the change in FDG uptake when comparing preinduction and postinduction values had strong power to predict pathologic response and outcome after combined modality treatment (Fig. 21-7). In a recent meta-analysis, PET had a sensitivity of 83% and a specificity of 84% in the prediction of pathologic response.¹¹¹ With the advent of endoscopic baseline mediastinal staging to confirm N2/N3 disease, the postinduction assessment can be based on primary tumor response by serial PET and lymph node assessment by a mediastinoscopy after induction therapy. In one model the combination of lymph node involvement and primary tumor response on PET could discriminate “good prognosis” patients (5-year survival 62%) from “poor prognosis” patients (only 6%, hazard ratio 0.18).¹¹² In the setting of induction chemoradiotherapy, there was a separation in prognosis as well, with a 5-year survival of 70% in the group with good PET response and 22% in the group with poor PET response.¹¹³

For *nonresectable stages I–III NSCLC* treated with radical radiotherapy, the data are in line with the findings in

eTable 21-1 Results of PET and Integrated PET/CT in Restaging after Induction Treatment for Locally Advanced NSCLC

*All patients received induction chemotherapy; the RT% indicates what percentage received radiotherapy in combination. CT, Computed tomography; N, number of patients; NSCLC, non-small cell lung cancer; PET, positron emission tomography; RT, radiotherapy.

operable disease. Indeed, early PET responses in the third week of radiotherapy correlated with prognosis after radiotherapy alone, or sequential or concurrent chemoradiotherapy: 2-year survival was 92% for responders versus 33% for nonresponders.^{114,115} PET obtained after completion of chemoradiotherapy also could discriminate prognosis, with complete metabolic responders having a median of 31 months versus 11 months for incomplete metabolic responders, and outperformed CT response, stage, or pretreatment performance.^{116,117} In patients with locally advanced disease treated with concurrent chemoradiotherapy, after completion of treatment, PET has an accuracy of about 90% for predicting tumor response.¹¹⁸ PET has also been used to predict tumor control during radiation treatment, with a sensitivity of 100% and specificity of 63%, and a tumor control detection probability of 80%.¹¹⁹ One study suggested that, compared to CT, PET better identified relapse after definitive chemoradiotherapy and that patients evaluated by PET had a better outcome when referred to salvage surgery, with a median overall survival of 12 months in patients operated for relapse on CT versus 43 months for patients operated for relapse on PET.¹²⁰

In patients with *stage IV* NSCLC, effective systemic chemotherapy causes a rapid decrease in FDG uptake on PET during the first cycle, and therefore PET could identify chemotherapy responders and nonresponders at an early treatment stage.^{121,122} Targeted therapies are advancing at a rapid pace in the treatment of NSCLC, and conceptually PET might be of great interest in the assessment of response to these therapies. Two independent studies have shown that early PET can predict progression-free and overall survival in patients treated with erlotinib, even in the absence of a CT response.^{123,124}

FOLLOW-UP

After therapy of NSCLC, early detection of recurrence is important because salvage therapies can be useful, especially in asymptomatic locoregional recurrences.

Selective use of PET can be recommended for the evaluation of a suspected local recurrence on conventional radiologic imaging in lung cancer patients previously treated for early-stage NSCLC with curative intent. Two prospective studies compared the differential diagnostic performance of PET and CT in the early detection of local recurrence^{125,126}; in both, the accuracy of PET was better than that of CT (93% versus 82%; 96% versus 84%). Several prospective series in patients with a residual thoracic abnormality after treatment addressed the value of PET to differentiate between local recurrence and residual nonspecific post-treatment changes.¹²⁵⁻¹³² An SUV cutoff of 2.5, differentiating benign from malignant lesions, as suggested for newly diagnosed lung lesions, had a sensitivity ranging from 97% to 100% and a specificity ranging from 62% to 100%.

Surveillance by PET/CT every 6 to 12 months after a treatment with curative intent (surgery or SABR) for early-stage NSCLC cannot be recommended. Despite several reports of a better sensitivity to detect disease recurrence on PET/CT in asymptomatic patients compared to chest CT scan alone, no survival benefit has been demonstrated in the postoperative follow-up setting. Moreover, false-positive findings are not infrequent after SABR.^{109,133-135}

NEW TRACERS

PET tracers have been developed for a whole range of biologic and pathophysiologic processes. One area of great interest has been the imaging of proliferation, a key hallmark of cancer cells. ¹⁸F-fluorodeoxythymidine (FLT) is a thymidine analogue labeled with the positron emitter fluorine-18.¹³⁶ Upon cell entry, FLT is phosphorylated by thymidine kinase type 1 but is not further metabolized and thus also not incorporated into newly synthesized DNA. Thymidine kinase type 1 is a major enzyme within the DNA salvage pathway, and its activity is strongly correlated with cellular proliferation, because it is upregulated before and during DNA synthesis. A recent meta-analysis provides strong evidence for the relation between FLT uptake and KI-67 score in a range of tumor types, including lung cancer.¹³⁷ FLT uptake in malignant tumors is lower than FDG uptake, resulting in a decreased sensitivity for diagnosis and staging.¹³⁸ For the assessment of response to anti-epidermal growth factor receptor therapy, initial results with FLT were encouraging because changes in FLT uptake early in the course of therapy predicted progression-free survival.¹³⁹ More recent studies comparing FLT and FDG in a similar therapeutic setting confirmed the potential of FLT, but nonetheless FDG was shown to be a better predictor of response.^{123,124}

Hypoxia within lung tumors can be depicted using tracers that accumulate in tissue having low oxygen tension, such as ¹⁸F-fluoromisonidazole and ⁶⁴Cu-diacetyl-bis(N4-methylthiosemicarbazone).¹⁴⁰ Both tracers undergo reduction under hypoxic conditions and subsequently bind to intracellular macromolecules. Because tumor hypoxia is an important component of resistance to radiotherapy, noninvasive measurement of hypoxic areas could direct increased radiation doses to hypoxic areas and perhaps improve locoregional tumor control.

Another interesting potential avenue is the use of radiolabeled drugs to determine biodistribution and tumor targeting.¹⁴¹ Tyrosine kinase inhibitors and chemotherapeutic agents can be labeled using carbon-11 and fluorine-18, resulting in ¹¹C-gefitinib, ¹⁸F-gefitinib, ¹¹C-erlotinib, and ¹¹C-docetaxel. ¹¹C-docetaxel has been studied in lung cancer patients, and the uptake of the tracer was predictive of response measured on subsequent CT.¹⁴² Monoclonal antibodies such as bevacizumab can also be labeled using zirconium-89, which has a half-life of 78 hours with kinetics matching those of monoclonal antibodies.

Key Points

- PET improves the accuracy of diagnosis of solitary pulmonary nodules, because their FDG-uptake pattern improves the comprehensive assessment of the probability of malignancy when combined with demographic, clinical, and CT characteristics.
- Combination PET/CT more accurately stages lung cancer than conventional imaging alone and leads to better treatment choices in a substantial proportion of patients with *non-small cell lung cancer* (NSCLC).

- The uptake of FDG may correlate with the aggressiveness and prognosis of NSCLC.
- The use of PET for diagnosis or staging is cost-effective in NSCLC patients with a potential for cure.
- PET has been shown to be most useful in guiding decisions about combined modality treatment in patients with locally advanced NSCLC.
- PET/CT is not indicated for standard patient follow-up after curative treatment for malignancy but is useful to characterize abnormal findings detected on conventional imaging.
- PET appears to be as useful in the assessment of small cell lung cancer and mesothelioma as in NSCLC but is supported by less abundant data; PET using special neuroendocrine tracers is helpful in patients with bronchial carcinoid tumors.
- Current research with PET is focusing on PET/magnetic resonance applications and on new tracers for molecular imaging and response prediction, which may guide targeted therapies and individualized radiotherapy.

INTRODUCTION AND HISTORICAL BACKGROUND

Flexible bronchoscopy (FB) is one of the prime examples of an area of pulmonary medicine transformed by technological advances. Today it has become one of the most frequently performed invasive procedures in pulmonary medicine. The use of bronchoscopy for *diagnosis* is covered in this chapter, and the use of bronchoscopy for *therapy* is covered in Chapter 23. Diagnostic bronchoscopy can also be divided into *basic* procedures, those available to most facilities and with significant evidence to support their use, and *advanced* procedures, those available only in some centers and still undergoing investigation to determine their most appropriate uses.

Gustav Killian performed the first bronchoscopy in 1897 to extract a piece of a pork bone from the right main bronchus.¹ From that meager beginning, the technology in bronchoscopy has advanced exponentially. In 1966 the flexible bronchoscope was introduced into clinical practice by Shigeto Ikeda.² Currently this instrument is one of the most important tools for diagnosis and treatment of pulmonary diseases.

Bronchoscopy can be easily performed in an outpatient setting, under moderate sedation and local anesthesia. Compared with FB, rigid bronchoscopy is now primarily used for selective indications such as massive hemoptysis and therapeutics (see Chapter 23).³⁻⁶

INDICATIONS

The indications for diagnostic FB are broad and growing (Table 22-1). Nonetheless, certain conditions are not considered indications for FB. For example, FB is not indicated to evaluate patients with cough unless the cough fails to respond to conventional treatment or if there is a change in its character. Similarly, bronchoscopy is not indicated to evaluate patients with isolated pleural effusion or atelectasis,⁷⁻⁹ and its use to remove secretions during acute exacerbations of chronic obstructive lung disease is also considered inappropriate.¹⁰ FB also has little role in finding synchro-

nous lesions in patients undergoing lung resection of a solitary pulmonary nodule suspected to be primary bronchogenic carcinoma.¹¹ Absolute and relative contraindications to performing FB are presented in Table 22-2.

PROCEDURE

FB is usually performed via the oral or the nasal route.¹² Either route provides excellent access to the lower airways. By either route, attention should also be given to the upper airway. In particular, bronchoscopy performed for the evaluation of hemoptysis or wheezing should include a careful evaluation of the upper airway, including the nasopharynx and oropharynx and vocal cords.

SEDATION AND ANESTHESIA

The need for sedation during FB remains a matter of some debate in the literature.¹³⁻¹⁵ The purpose of sedation is to improve patient comfort and add to the ease of the procedure for the bronchoscopist.^{16,17} Although bronchoscopy can be carried out without sedation,^{18,19} most are performed under moderate sedation.²⁰⁻²³

Intravenous preparations of various sedatives such as diazepam, midazolam, lorazepam, morphine sulfate, fentanyl, and hydrocodone have been used either alone or in combination based on the bronchoscopist's preference and the availability of the drug.²⁴⁻²⁹ Fentanyl has a greater analgesic potency than morphine.²⁵ Hydrocodone has a greater antitussive property than codeine but less than that of morphine.³⁰ Due to its rapid onset and anxiolytic and amnestic properties, midazolam is one of the most commonly used sedatives; sedation with midazolam in FB improves the patient's comfort and decreases complaints, without causing significant hemodynamic compromise. It should be offered to the patient on a routine basis.^{31,32}

The combination of a benzodiazepine and an opioid has been shown to be safe and synergistic for the purposes of sedation during FB.^{28,33} Because the combination of benzodiazepines and opiates may cause hypoventilation, particularly in patients with preexisting respiratory failure, patients should be appropriately monitored.³⁴ The combination of

Table 22-1 Indications for Diagnostic Flexible Bronchoscopy (Adult)

Hemoptysis
Wheeze and stridor: suspected stricture, upper airway obstruction
Lung opacities of unknown cause
■ Suspected pulmonary infections not responding to conventional treatment
(a) Localized
(b) Diffuse
■ Lung opacities in an immunocompromised host
■ Recurrent or unresolved pneumonia
■ Cavitory lesion
■ Interstitial opacities
■ New pulmonary nodule
Unexplained lung collapse
Suspected or known bronchogenic carcinoma
■ Positive or suspicious sputum cytologic findings
■ Staging
■ Follow-up after endobronchial treatments
Mediastinal and hilar lymphadenopathy and masses
Lung transplantation
■ Inspect airway anastomosis
■ Rejection surveillance
Esophageal cancer evaluation
Endotracheal intubation
■ Confirm tube position
■ Evaluate for tube-related injury
Evaluation for foreign body aspiration
Chest trauma
■ Rule out rupture of central airways
■ Examine for aspirated contents
Evaluation following burns or chemical injury to the airways
Unexplained superior vena cava syndrome
Unexplained vocal cord paralysis or hoarseness
Suspected fistulas
■ Bronchopleural
■ Tracheoesophageal and bronchoesophageal
■ Tracheoarterial or bronchoarterial
■ Iatrogenic (postsurgical)

Table 22-2 Contraindications for Flexible Bronchoscopy**ABSOLUTE**

Uncorrectable hypoxemia
 Lack of patient cooperation
 Lack of skilled personnel
 Lack of appropriate equipment and facilities
 Unstable angina
 Uncontrolled arrhythmias

RELATIVE

Unexplained or severe hypercarbia
 Uncontrolled asthma
 Uncorrectable coagulopathy
 Unstable cervical spine
 Need for a large tissue specimen for diagnosis
 Debility, advanced age, malnutrition

hydrocodone and midazolam reduces cough during FB without causing significant desaturation and improves the patient's tolerance for the procedure.^{28,33}

Dexmedetomidine (Precedex, Dexdomitor) also has favorable properties of sedation, sympatholysis, analgesia, and a low risk for apnea. These properties suggest that dexmedetomidine may be useful in procedural sedation. However,

it has been shown that dexmedetomidine as a sole agent is unable to provide adequate sedation for awake diagnostic FB without the need for rescue sedation in a large proportion of patients.³⁵

Dextromethorphan can also be given orally 90 minutes before the procedure to improve cough suppression during the procedure.³⁶

Interestingly, according to some surveys, 16% to 21% of physicians use deep sedation or general anesthesia for FB.^{20,22} Use of propofol alone is as effective and safe as combined sedation in patients undergoing FB under conscious sedation, thus representing an appealing option if timely discharge is a priority.³⁷ Deep sedation with propofol for bronchoscopy has gained popularity in recent years, although concern has been raised regarding its potential ability to induce severe respiratory depression. In one prospective study the use of small boluses of propofol at short intervals with monitoring of transcutaneous carbon dioxide level was found to be safe; the authors concluded that propofol used in this manner does not cause excessive respiratory depression and represents an excellent alternative to traditional sedation agents.³⁸ In another prospective study the combination of propofol and hydrocodone was safe and better for cough suppression than propofol alone in FB.³⁹

Fospropofol disodium is a water-soluble prodrug of propofol. A subset analysis was undertaken among elderly patients (≥ 65 years) undergoing FB; fospropofol provided safe and effective sedation, rapid time to fully alert status, and high satisfaction, which were comparable with outcomes in younger patients.⁴⁰

Patients with *human immunodeficiency virus* (HIV) infection, recipients of stem cell transplantation, lung transplant recipients for cystic fibrosis, and drug users usually require higher doses of sedatives than other patients.³¹⁻⁴³ Additionally, because protease inhibitors used in patients with HIV infection have been shown to extend the half-life of benzodiazepines significantly, many institutions in the United States encourage the use of deep sedation in these patients instead.

LOCAL ANESTHESIA

Although nerve blocks can be used to provide excellent analgesia to the airway, physicians generally rely on topical administration of local anesthetic agents. Lidocaine is the most commonly used drug for providing topical anesthesia.⁴⁴ It offers a relatively wide margin of safety with a rapid onset and sufficient duration of action to allow completion of most bronchoscopic procedures. The gel preparation of lidocaine is preferred over the spray for nasal anesthesia.⁴⁵⁻⁴⁷ Given that sensory anesthesia is not dependent on the concentration of lidocaine, 1% is preferred because larger volumes can be instilled to cover a greater surface area of the mucosa before toxic dosages are reached.^{48,49} The oropharynx can be anesthetized with 2% to 4% lidocaine applied as a spray, nebulized solution, or gargles.

The vocal cords as well as the endobronchial tree are anesthetized by direct instillation of lidocaine via the working channel of the bronchoscope. The total dose of lidocaine should be limited to 8.2 mg/kg in adults, with extra caution in older adults or those with liver, renal, or cardiac impairments.²⁴

Anticholinergic agents such as atropine and glycopyrrolate have been commonly used as premedication for FB^{50,51} with the aim to reduce the bronchial secretions and suppress vagal overactivity. Several studies have shown that anticholinergics offer little advantage as premedications, and their use should be abandoned.⁵²⁻⁵⁴

MONITORING

To ensure adequate oxygenation (oxygen saturation of >92%) and hemodynamic stability, pulse oximetry, heart rate, and blood pressure are monitored throughout the procedure. There should be intravenous access and equipment for resuscitation. Supplemental oxygen should be available. At many institutions, continuous end-tidal carbon dioxide monitoring is used to assess ventilation. All FB procedures are performed observing universal precautions. Following each procedure, the instrument is thoroughly disinfected or sterilized according to recently published consensus statements.^{55,56,56a}

BASIC DIAGNOSTIC BRONCHOSCOPY

The standard procedure for FB involves a thorough examination of the entire tracheobronchial tree in a systematic fashion, from the upper airway and vocal cords to the trachea and carina, major bronchi, and the segmental bronchi in each of the five lung lobes. A thorough understanding of normal features can allow detection of abnormalities in anatomy (e.g., missing or duplication of bronchi), shape (e.g., narrowing or distortion), changes in the anatomy with breathing (e.g., collapse), or endobronchial mucosa (e.g., induration, friability, erythema, lesions). A bronchoscopy of a patient with a relatively normal tracheobronchial tree is shown in [Video 22-1](#).

Examination of the upper airway can be instructive. The vocal cords may be involved with infections ([Fig. 22-1](#)) or malignancy; the cords may be paralyzed as a result of interruption of the recurrent laryngeal nerve or erythematous or edematous due to gastroesophageal reflux. The trachea may be abnormal owing to either congenital or acquired

conditions ([Fig. 22-2A and B](#)). The endobronchial mucosa exhibits characteristic changes due to infiltrative or systemic conditions (see [Fig. 22-2C and D](#)). Endobronchial lesions may be caused by a multitude of conditions, including inflammatory, malignant, or infectious disease, or by foreign bodies ([Fig. 22-3](#)). Attention should also be paid to the normal expiratory collapse of the central airway as well as to the presence of excessive dynamic airway collapse/tracheobronchomalacia.^{57,57a-e}

BRONCHOALVEOLAR LAVAGE

Bronchoalveolar lavage (BAL) has become an important clinical and investigational tool.^{58,59} It is a standard diagnostic procedure in all patients with diffuse lung abnormalities of unknown cause whether an infectious, noninfectious, immunologic, or malignant cause is suspected.^{60,61} BAL allows the recovery of both cellular and noncellular components of the epithelial (alveolar) lining fluid and epithelial surface of the lower respiratory tract. Components of the BAL fluid represent the inflammatory and immune status of the lower respiratory tract and the alveoli^{58,62} ([Fig. 22-4](#)). BAL, which samples the distal air spaces, differs significantly from a bronchial washing, which samples the large airways via aspiration of small amounts of instilled

Figure 22-1 Vocal cord candidiasis in an immunocompromised host.

Note the black pigmentation of the tumor. **B**, *Aspergillus niger* infection in a lung transplant recipient. The black pigment indicates the fungus and the white pigment indicates calcium oxalate crystals produced by the fungus. **C**, Recurrent respiratory papillomatosis involving the trachea. Note the typical mulberry appearance. **D**, A foreign body in the left main bronchus. The object is a camera used for capsule endoscopy that was aspirated into the lungs. (D, Courtesy Dr. Thomas Gildea.)

Figure 22-4 Schematic presentation of the constituents of the bronchoalveolar lavage fluid. (From Kuvuru MS, Dweik RA, Thomassen MJ: Role of bronchoscopy in asthma research. *Clin Chest Med* 20(1):153-189, 1999; modified, with permission, from Walters EH, Ward C, Xun Li: Bronchoalveolar lavage in asthma research. *Respirology* 1:233-245, 1996.)

saline.^{61,63,64} BAL should be considered a standard procedure in the evaluation of diffuse lung diseases, suspected infection, or malignancy, especially when the bleeding risk prohibits either bronchial brushing, *transbronchial biopsy* (TBB), or *transbronchial needle aspiration* (TBNA).

For diffuse opacities, any area can be chosen for BAL; however, in such cases, either the right middle lobe or the lingula is preferred because, in a supine patient, gravity assists the recovery of a maximal amount of BAL fluid return.^{59,60,65} In the case of localized disease, lavage should be performed in the area of focal radiographic abnormality,^{61,63,65} and for maximal recovery, the patient can be positioned appropriately to improve recovery from the desired segment. “Good wedge” position usually means that the bronchoscope is advanced as far as possible without losing the view of the distal lumen. In this optimal position, a slow, manual gentle aspiration, without allowing the airway walls to collapse, tends to maximize the lavage return.

BAL has significantly improved the diagnostic workup of lung diseases, whether diffuse or localized. In pulmonary alveolar proteinosis, it has both diagnostic and therapeutic value.^{60,66-69} In an international statement on the major

interstitial lung diseases, BAL is considered to be helpful in strengthening the diagnosis of sarcoidosis in the absence of a tissue diagnosis, by finding a lymphocytosis (>25%) and a CD4/CD8 ratio greater than 4.^{70,71} BAL may be a useful tool in the diagnosis of peripherally located primary lung cancer, with an overall diagnostic yield range of 33% to 69%, being exclusively diagnostic in 9% to 11% of cases.⁷²⁻⁷⁹ Numerous case reports confirm the ability of BAL to diagnose leukemia and lymphomatous pulmonary involvement as well as plasma cell dyscrasia.⁸⁰⁻⁸² Finding asbestos bodies in BAL fluid may correlate with occupational exposure, yet in itself, it is not proof of an asbestos-related disease.^{83,84} The presence of more than 25% eosinophils in the BAL fluid confirms the diagnosis of eosinophilic lung diseases, and the presence of more than 4% CD1⁺ Langerhans cells confirms a diagnosis of Langerhans cell histiocytosis, albeit with low sensitivity.⁸⁵ In chronic beryllium disease, lymphocytes from the BAL proliferate when stimulated in vitro with soluble beryllium salts, with a sensitivity and specificity approaching 100%; this lymphocyte test has become a valuable diagnostic tool for this condition and has replaced open-lung biopsy.^{86,87}

In patients with ventilator-associated pneumonia, a positive quantitative culture (>10⁴ colony-forming units (CFU)/mL) on BAL fluid may be clinically useful with a sensitivity of 22% to 93% and a specificity of 45% to 100%, depending upon the clinical status of the patient.⁸⁸⁻⁹⁵ BAL is also a useful tool in the diagnosis of pulmonary infections in immunocompromised patients, with the reported yield as high as 93%⁹⁶⁻¹⁰³ (Fig. 22-5). Thus, in certain conditions, BAL findings can be diagnostic and thereby avoid the need for either TBB or open-lung biopsy (Table 22-3). In other settings, although not diagnostic, BAL can be used as an adjunct to the diagnosis when interpreted in the context of the entire clinical picture.

While performing BAL in an immunocompromised host and if invasive *Aspergillus* infection is suspected, the fluid should be submitted for galactomannan cell wall antigen detection using an enzyme immunoassay. The sensitivity and specificity of elevated galactomannan levels in BAL fluid are of value in immunocompromised patients. According to a recent meta-analysis, the sensitivity, specificity, and accuracy are reported to be 79%, 86%, and 89%, respectively. It needs to be pointed out that concomitant use of certain antibiotics such as piperacillin-tazobactam,

Figure 22-5 Bronchoalveolar lavage specimen reveals a larva of *Strongyloides stercoralis*. (Courtesy Dr. Suhail Raoof.)

Table 22-3 Diseases in Which Bronchoalveolar Lavage Can Be Diagnostic

Opportunistic infections (<i>Pneumocystis jirovecii</i> , fungi)
Invasive aspergillosis (via galactomannan levels)
Pulmonary alveolar proteinosis
Alveolar hemorrhage syndrome
Malignant opacities (solid tumors, lymphoma, leukemia)
Eosinophilic lung disease
Chronic beryllium disease
Langerhans cell histiocytosis

amoxicillin, or amoxicillin-clavulanate and all fermentation products of *Penicillium* species may produce false-positive results. Besides, the test may also have cross reactivity with *Histoplasma capsulatum* cell wall antigen. Hence the results should be interpreted in the context of the total clinical picture and rechecked periodically.¹⁰⁴

The most common complications associated with BAL are fever, which can be seen in up to 30% of patients, and transient hypoxemia, which is readily handled with supplemental oxygen.

BRONCHIAL WASHINGS

Bronchial washings are obtained by advancing the bronchoscope into an airway, instilling 10 to 20 mL of sterile saline, and then quickly aspirating the instilled saline into a specimen trap. The utility of bronchial washings is largely for the diagnosis of airway diseases, including primary or metastatic lung carcinoma and fungal or mycobacterial infection. Of the various bronchoscopic procedures, bronchial washing is the easiest to perform but has the lowest yield (sensitivity, 27% to 90%),¹⁰⁵⁻¹¹⁰ with a higher yield for central lesions.^{108,111-113} Bronchial washings are an inexpensive adjunct and should be collected during a diagnostic bronchoscopy when appropriate because, even though by a small percentage, they can increase the overall diagnostic yield of the procedure.^{108,114,115}

BRONCHIAL BRUSHINGS

Bronchial brushings were analyzed for the first time in 1973 and showed highly suspicious cytologic findings in most cases with lung cancer.¹¹⁶ In general, bronchial

brushings provide diagnostic material in 72% (44% to 94%) of patients with central lung cancers and 45% of patients with peripheral lesions, when obtained under fluoroscopic guidance.¹¹⁷ When bronchial brushing is combined with *endobronchial biopsy* (EBB) of central lesions, the diagnostic yield of FB increases to between 79% and 96%.¹¹⁸ We usually perform brushing after obtaining all the other bronchoscopy specimens to avoid bleeding or cell distortion interfering with obtaining or interpreting subsequent samples. The diameter or the length of the brush has not been shown to affect the diagnostic yield from the bronchial brushing.

Protected Specimen Brush

Protected specimen brush was first described in 1979 by Wimberley and coworkers¹¹⁹ as a technique to establish an accurate diagnosis in patients with suspected pneumonia. Brushing specimens are collected using a special brush that is enclosed within a double catheter sheath. The catheter is closed off at its distal end by a wax plug, which can be easily dislodged before obtaining the specimen. The purpose of the catheter sheath and wax plug is to prevent contamination of the brush with oropharyngeal flora that remain inside the working channel of the bronchoscope.

In patients with ventilator-associated pneumonia, the sensitivity of protected specimen brush ranges from 58% to 86% and the specificity from 71% to 100%.^{120,121} For now, the procedure appears to have lost popularity against empiricism for the diagnosis of ventilator-associated pneumonia; however, when it is used, quantitative cultures with a cutoff value of greater than 10^3 CFU/mL should be obtained to optimize its accuracy (see also Chapter 34).

ENDOBONCHIAL BIOPSY

EBB is an essential and technically simple tool in the diagnosis of endobronchial neoplasms as well as for inflammatory conditions such as sarcoidosis and amyloidosis. When the forceps are open, they are advanced onto the target and closed, thereby gripping the target. The forceps are briskly pulled back, taking a sample of the endobronchial lesion 2 to 4 mm in diameter. The forceps and biopsy specimen are then pulled out through the working channel, and the tissue sample is collected in saline or fixative. EBB is used for lesions directly visualized during bronchoscopy. It provides histologic specimens, whereas bronchial washing provides only cytologic samples. The reported diagnostic yield of EBB is 80% with a range of 51% to 97% depending upon the patient population.^{105,106,117,122-124} The number of biopsy specimens required for optimal diagnostic yield varies according to the suspected diagnosis. Three biopsy specimens of an endobronchial lesion suspected to be bronchogenic carcinoma can provide a diagnostic yield of over 97%.¹²⁵ Biopsy of the surface of endobronchial tumors may be falsely negative if there is surface necrosis; in such circumstances, needle sampling deeper into the mass may be diagnostic.

TRANSBRONCHIAL BIOPSY

TBB is the technique by which a piece of lung parenchyma is obtained by using flexible forceps positioned distally via

FB. TBB specimens can be obtained blindly or with guidance by fluoroscopy, *computed tomography* (CT), or radial-probe endobronchial ultrasonography. In many instances TBB can obviate the need for an open-lung biopsy; however, certain diagnoses such as idiopathic pulmonary fibrosis generally require larger tissue samples than those that can be obtained bronchoscopically. TBB is diagnostically useful in 38% to 79% of patients (average sensitivity, 52%) depending upon the underlying disease.¹²⁶⁻¹³⁰ For example, in sarcoidosis, TBB has a diagnostic yield of 40% to 90%,^{131,132} although recent studies indicate that *endobronchial ultrasonography-guided TBNA* (EBUS-TBNA) of mediastinal/hilar nodes may have a greater diagnostic yield.¹³³ TBB has also been shown to be diagnostic in up to 10% to 40% of cases of Langerhans cell histiocytosis,¹³⁴ 88% to 97% in *Pneumocystis jirovecii* pneumonia,^{98,135} and 57% to 79% in lung infections caused by *Mycobacterium tuberculosis*.¹³⁶ In patients suspected of having pulmonary alveolar proteinosis, its diagnostic yield has been reported to be as high as 100% (Fig. 22-6).

The diagnostic yield of TBB increases with the number of biopsy specimens obtained.¹³⁷ Usually 6 to 10 biopsy specimens are obtained under fluoroscopic guidance. However, the use of fluoroscopy is not mandatory in patients with diffuse parenchymal disease, and biopsy specimens can be obtained by assessing the proximity to the pleura as guided by the patient's perception of chest pain. The yield of TBB for malignant peripheral lesions more than 2 cm in diameter was also reported to be 70% in a recent study, even without fluoroscopic guidance.¹³⁸ When performed in association with bronchial brushings and TBNA, TBB adds to the diagnostic yield of FB for peripheral lung cancers.^{112,117,139-144}

The success of lung transplantation cannot be imagined without the contributions from FB and especially TBB. In lung transplant recipients, TBB helps in diagnosing or ruling out acute cellular rejection. It also helps establish the diagnosis of antibody-mediated rejection as well as that of chronic rejection, albeit with lower yield. To date, however, there are no gold standard findings for diagnosing rejection in the lung transplant population.

Pneumothorax and hemorrhage are the most feared complications following TBB, with an incidence of up to 5%

of cases. Renal insufficiency (*blood urea nitrogen* [BUN] level > 30 mg/dL [10.7 mmol/L] and creatinine level of >3 mg/dL [265 μ mol/L]) and other coagulopathies are considered risk factors for bleeding following TBB.^{145,146} TBB can be safely performed while patients are receiving aspirin or non-steroidal anti-inflammatory drugs; however, clopidogrel bisulfate should be withheld for at least 5 to 7 days before the procedure.^{147,148}

TRANSBRONCHIAL NEEDLE ASPIRATION

TBNA is a sensitive, accurate, safe, and cost-effective technique in the diagnosis and staging of lung cancer,^{144,149-154} and it can also be applied for the diagnosis of nonmalignant diseases such as sarcoidosis¹⁵⁵⁻¹⁵⁹ (Video 22-2). Despite proven advantages, the practice of TBNA remains underutilized.¹⁶⁰⁻¹⁶² There are no absolute, specific contraindications for TBNA.

Diagnosis and staging of bronchogenic carcinoma, lymphoma, and sarcoidosis can be established using 21- or 22-gauge cytology needles.^{133,161,163,164} For the diagnosis of lung cancer, the reported sensitivity, specificity, and accuracy of TBNA are 60% to 90%, 98% to 100%, and 60% to 90%, respectively.¹⁶³⁻¹⁷⁰ For mediastinal staging, the overall sensitivity, specificity, and accuracy of TBNA are 50%, 96%, and 78%, respectively.¹¹⁷ Judicious use of TBNA can thus reduce the need for surgical staging. In the diagnosis of involvement of mediastinal or hilar lymph nodes by sarcoidosis or tuberculosis, TBNA can be useful as well.¹⁵⁵⁻¹⁵⁹ (Fig. 22-7). In cases with pulmonary nodules, TBNA increases the diagnostic yield of FB by 25%.¹³³ TBNA can also be safely performed in mechanically ventilated patients.¹⁶⁸

The procedure of TBNA is safe, with an overall major complication rate of approximately 0.26%. Complications include damage of the working channel of the bronchoscope, fever, bacteremia, and bleeding from the puncture site (Fig. 22-8).^{139,144,161} Use of CT, fluoroscopy, and ultrasonographic guidance has been shown to improve the yield of TBNA.^{171,172,172a-d}

Figure 22-6 Transbronchial biopsy specimen confirms the diagnosis of pulmonary alveolar proteinosis. Note periodic acid-Schiff stain-positive material filling up the alveolar spaces.

Figure 22-7 Transbronchial needle aspiration specimen obtained using a 19-gauge histology needle reveals noncaseating granulomas under high-power magnification ($\times 200$ original magnification) following hematoxylin and eosin stain.

Figure 22-8 Complication of transbronchial needle aspiration. **A**, On day 1, mediastinal hemorrhage is noted (arrows). **B**, By day 6, the abnormality has resolved. (Courtesy Dr. Stefano Gasparini)

ENDOBONCHIAL ULTRASONOGRAPHY

Endobronchial ultrasonography (EBUS) is a bronchoscopic technique that uses ultrasound to visualize structures within and adjacent to the airway wall. There are two types of EBUS device: *radial-probe EBUS* (RP-EBUS) (Fig. 22-9A–C) and *convex-probe EBUS* (CP-EBUS) (Fig. 22-9D).^{173,174}

RP-EBUS is a technique in which a small ultrasound probe (1.4 to 2.8 mm diameter, 20 MHz) is introduced into the airways through the working channel of the FB to obtain ultrasonographic images of the peribronchial tissues. Because the RP-EBUS is placed in the endobronchial tree through the working channel of the conventional bronchoscope, it precludes real-time sampling. Using a fluid-filled balloon around the probe, the structure of the airway wall can be studied as, for example, to determine the depth of tumor invasion or to assess the structure of the bronchial wall in diseases such as tracheobronchomalacia. RP-EBUS provides a 360-degree view of the peribronchial tissue with high-resolution ultrasonographic views of the tissue layers in close contact with the probe or the fluid balloon (see Fig. 22-9C).

For obtaining samples using the RP-EBUS, the RP-EBUS is introduced via a guide sheath and is advanced into the peripheral pulmonary lesion under bronchoscopic guidance. Once the lesion is identified with ultrasonographic images, the probe is removed leaving the guide sheath in place; endobronchial accessories are inserted through the sheath to the peripheral lesion to obtain diagnostic specimens (see Fig. 22-9B and C). Using this technique, the diagnostic yield of FB for peripheral lung lesions less than 3 cm in size has been improved to nearly 75%.¹⁷⁵ During the early

years of EBUS application, the radial probe was also used to guide TBNA in the diagnosis of mediastinal disease and for the staging of non-small cell carcinoma. However, because real-time guidance is not possible with the RP-EBUS, in recent years, sampling of mediastinal pathologic conditions has been carried out with CP-EBUS bronchoscope (see Fig. 22-9D).

CP-EBUS is an endobronchial ultrasonographic technique that allows real-time imaging during sampling. A 7.5-MHz curved ultrasound transducer integrated into the distal tip of the bronchoscope delivers sound waves in a linear or longitudinal fashion encompassing a 55-degree area. The scope has an outward diameter of 6.9 mm and a 30-degree forward endoscopic oblique view.^{176,177} While the site is being imaged ultrasonographically, the TBNA specimen is obtained with a specially designed 21- to 22-gauge needle inserted through the working channel of the scope to obtain a cytologic examination (Video 22-3). The procedure is performed either under moderate sedation or general anesthesia.

The primary role of CP-EBUS is in the nodal staging of non-small cell lung cancer. When mediastinal/hilar lymph nodes less than 20 mm in short axis, especially in the 4L station, need to be sampled, CP-EBUS-TBNA should be the preferred sampling method. For lesions that are paraesophageal, in the inferior mediastinum, or involve the left adrenal gland, *endoscopic* ultrasound-guided fine-needle aspiration may be a more appropriate initial sampling method. The combined use of EBUS-TBNA with endoscopic ultrasound-guided fine-needle aspiration has been shown to reduce the need for surgical sampling and, by accurately staging unresectable patients, to avoid “unnecessary thoracotomies.”^{172,178-180} In various reports of its value in staging for lung cancer, EBUS-TBNA has excellent sensitivity, specificity, positive predictive value, negative predictive value, and diagnostic accuracy of 95%, 100%, 100%, 90%, and 96%, respectively.^{179,181} Despite the cytologic nature of the EBUS-TBNA specimen, adequate tissue is easily obtained for molecular studies and genetic mutation analysis for personalized treatment for unresectable adenocarcinoma of the lung.¹⁸² Compared to that for conventional FB, the procedure for EBUS-TBNA takes longer and requires additional training. EBUS-TBNA is more expensive than conventional TBNA but could reduce expenses by limiting the number of more costly surgical procedures (Table 22-4). In the future EBUS-TBNA may have applications in the diagnosis of airway as well as pulmonary vascular disease.¹⁸³

Compared to mediastinoscopy, EBUS-TBNA was as effective in determining the pathologic lymph node state in prospective studies involving patients with potentially resectable lung cancer.¹⁸⁴ The specificity and positive predictive value for both techniques was 100%, whereas the sensitivity, negative predictive value, and diagnostic accuracy were 81%, 91%, and 93%, respectively, for EBUS-TBNA and 79%, 90%, and 93%, respectively, for mediastinoscopy. These studies suggest that, when performed under general anesthesia, with rapid on-site cytologic examination, and using different needles for each lymph node station, EBUS-TBNA can replace mediastinoscopy for lymph node staging.¹⁸⁴

To determine whether an endobronchial lesion is invasive or resectable, we recommend use of RP-EBUS^{172,185,186} with a balloon sheath catheter. For sampling endobronchial

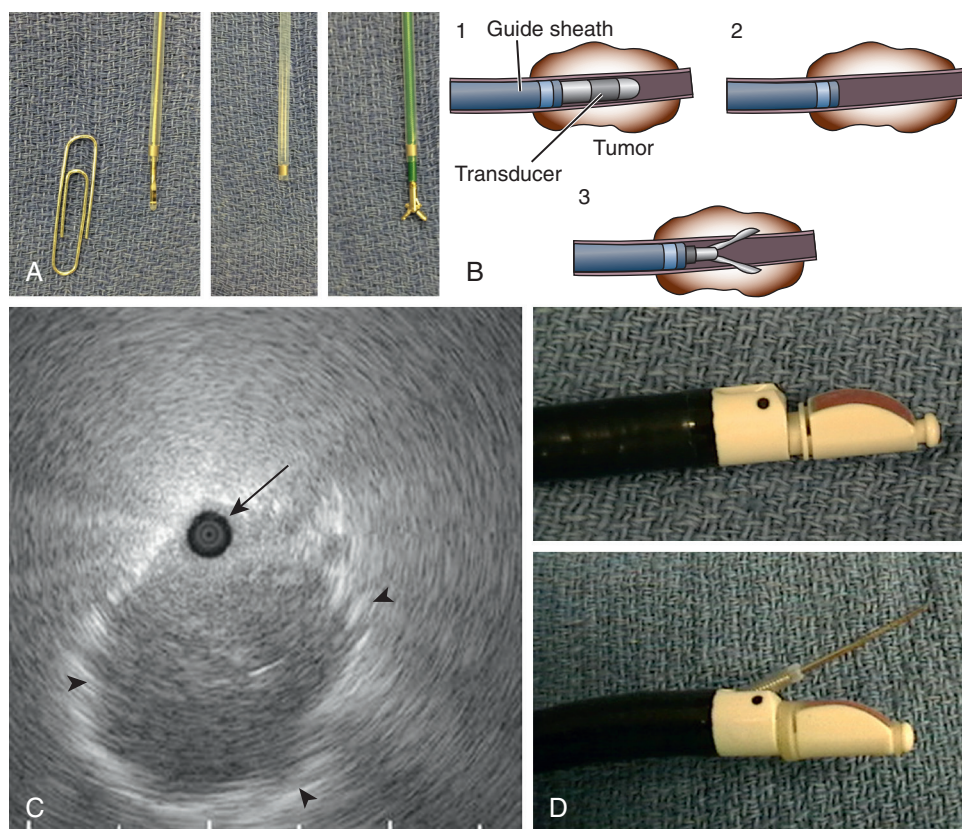

Figure 22-9 Endobronchial ultrasonography (EBUS) using radial probe (RP) or convex probe (CP). **A,** On the *left*, a radial probe is shown extending through a guide sheath. A paper clip is shown for scale. In the *middle* image, the sheath is shown with the probe removed. In the image on the *right*, a forceps is now extended through the guide sheath. **B,** Schematic representation of the technique of sampling a peripheral tumor using RP-EBUS through a guide sheath. Within the guide sheath, the probe is advanced to obtain ultrasonic images and position the guide sheath within the tumor (1); the probe is then withdrawn (2); the forceps is then advanced to the site of the tumor for sampling (3). **C,** Peripheral lung lesion through the eyes of the RP-EBUS. The lesion is indicated by a paucity of the ultrasonic pattern (arrowheads) shown below the dark bronchus (arrow). The “snowstorm” pattern above the bronchus is seen with normal lung parenchyma. **D,** Distal end of CP-EBUS bronchoscope before and after the sampling needle is extended.

Table 22-4 Endobronchial Ultrasonography

Advantages	Disadvantages
Outpatient procedure using local anesthesia and conscious sedation. Sampling of the high mediastinal, paratracheal, and subcarinal lymph nodes possible, similar to mediastinoscopy. Also allows sampling of hilar lymph nodes. High diagnostic yield. More invasive diagnostic procedures (e.g., mediastinoscopy) are frequently rendered unnecessary. Complications are uncommon, while sampling is performed in real time. Real-time imaging permits the sampling of lymph nodes that are smaller than 10 mm in short axis and/or near major blood vessels.	Cannot image or sample para-aortic and lower paroesophageal lymph nodes. Technically challenging. Not widely available. Only small (i.e., 21- and 22-gauge) needles can be used for EBUS-guided transbronchial needle aspiration. Benign condition may require histologic specimen.

EBUS, endobronchial ultrasonography.

lesions, EBUS-TBNA is seldom required, and EBB and conventional TBNA should be performed instead. To sample a peripheral pulmonary nodule, we suggest that RP-EBUS-guided TBB should be the first sampling procedure. RP-EBUS-guided TBB of peripheral pulmonary nodules detects malignant disease with a sensitivity and specificity of 73% and 100%, respectively.¹⁸⁷ The diagnostic yield of RP-EBUS-guided TBB is also higher than that of conventional TBB.^{172,180,188}

ADVANCED DIAGNOSTIC BRONCHOSCOPY

The following techniques are advancing the field of bronchoscopy using new technology either to improve imaging or to improve navigation to peripheral lesions. Their specific applications and benefit are still being determined, but they hold promise for extending the range of bronchoscopy for diagnosis of central or peripheral lesions.

Figure 22-10 Ultrathin bronchoscope with a flexible forceps inserted through the working channel. (Courtesy Dr. Rex Yung.)

ULTRATHIN BRONCHOSCOPY

The ultrathin bronchoscope currently being studied has an outer diameter of 2.8 mm and an inner channel diameter of 1.2 mm and is made up mainly of fiberoptic bundles (Fig. 22-10). This device has been developed to overcome the low diagnostic yield of FB for lesions less than 20 mm in diameter.¹⁸⁹⁻¹⁹² Complexities of the distal airway anatomy require fluoroscopic or CT guidance to maneuver the scope to peripheral lesions.¹⁹³ These bronchoscopes also can be used with ease in mechanically ventilated patients with small endotracheal tubes. Ultrathin bronchoscopes help in evaluating the nature and the extent of upper airway obstruction where there is a risk for completely compromising the airways with standard bronchoscopes.¹⁹² An ultrathin bronchoscope is also useful for defining the distal extent of an endobronchial tumor when it is causing significant airway obstruction.¹⁹⁴

CONFOCAL BRONCHOSCOPY

Fiberoptic confocal fluorescence microscopy is a new technique that produces microscopic imaging of a living tissue via a 1-mm fiberoptic probe that can be introduced through the working channel of the conventional bronchoscope. Confocal endomicroscopy is a feasible method for analyzing human airway wall architecture and endobronchial abnormalities in histologic detail in vivo. In a recent study, bronchial fiberoptic confocal fluorescence microscopy was performed at 488-nm excitation wavelength on two bronchial specimens ex vivo and in 29 individuals at high risk for lung cancer in vivo; the alterations in fluorescent signal appeared to originate from the elastin component of the basement membrane zone.¹⁹⁵ Alterations of the autofluorescence microstructure were observed in 19 of 22 metaplastic or dysplastic samples, 5 of 5 carcinomas in situ, and 2 of 2 invasive lesions, representing a minimally invasive method of studying specific basement membrane alterations associated with premalignant bronchial lesions in vivo. In the future the technique may be used to study bronchial wall remodeling in nonmalignant chronic bronchial diseases.

ELECTROMAGNETIC AND VIRTUAL BRONCHOSCOPIC NAVIGATION

Electromagnetic navigation (EMN) and virtual bronchoscopic navigation can be used to guide the bronchoscopist to

Figure 22-11 Electromagnetic navigation monitor. A pulmonary nodule is depicted in three different views. Right lower quadrant image exhibits the position of the microsensor (orange ring) in relation to the virtual pulmonary nodule (green circle).

lesions that cannot be visualized in the airways, because they are either distal or paratracheal. EMN creates an electromagnetic field around the chest of a patient undergoing FB, superimposes the field upon previously acquired three-dimensional CT images, and determines the position of a locatable guide containing sensors within the endobronchial tree.¹⁹⁶ Once steered into position, the guide is withdrawn, and biopsy tools are advanced through the guide sheath to obtain biopsy specimens at the site. In principle, the navigation system is similar to the global positioning system used in automobiles and airplanes. Virtual bronchoscopic navigation, on the other hand, creates a virtual bronchoscopic map from existing CT data and then suggests the best path to the target lesion.

EMN may improve the otherwise limited diagnostic yield of FB for peripheral lung lesions and solitary pulmonary nodules.¹⁶⁸ Recent studies have shown that EMN increases this yield to the range of 63% to 90%.¹⁹⁷⁻²⁰⁷ EMN and virtual bronchoscopic navigation are well tolerated and have proved to be both safe and useful in localizing small or fluoroscopically invisible lung lesions with a sufficient level of accuracy (Fig. 22-11).^{208,209} The ultimate value of these navigational aids and whether their benefits will justify their cost is not known.

AUTOFLUORESCENCE BRONCHOSCOPY

In the treatment of lung cancer, the best outcome is achieved if the lesion is discovered in the intraepithelial stage. However, intraepithelial neoplastic lesions are difficult to localize by conventional *white-light bronchoscopy* (WLB). *Autofluorescence bronchoscopy* (AFB) has been in use since 1988 as an aid to the diagnosis of bronchial precancerous lesions and early lung cancers.²¹⁰⁻²¹⁵ In this method, airways are illuminated by blue light. Fluorescence emitted from the mucosal surface is partially quenched in areas of dysplasia, a result that can be enhanced by video signal processing. Normal areas are usually exhibited in a green color, whereas the suspicious areas appear with reddish to brown discoloration (Fig. 22-12). Lesions detected by AFB include squamous cell cancer and the “pre-malignant” dysplasias of the squamous epithelium.²¹⁶ AFB can also capture the

Figure 22-12 Autofluorescence bronchoscopy. White-light image (left) versus autofluorescent image (right). A lesion that is poorly seen using white light (black arrow, left) becomes more evident under fluorescent light (white arrow, right). The brownish discoloration involving the posterior airway wall depicts an area suspicious for early lung cancer.

endobronchial extent of tumor; thus it can be helpful for deciding the line of resection preoperatively or planning endobronchial therapies.

Discrimination between cancerous or precancerous lesions and inflammation is not possible by endoscopic images alone, and a histologic diagnosis is still necessary.²¹⁰ In a multicenter study the combination of WLB and AFB had greater sensitivity (82.3%) for detecting dysplasia than WLB (57.9%) alone, although the benefit for detecting carcinoma *in situ* was not significant.²¹³ In various studies, although the specificity of AFB together with WLB is lower than that of WLB alone, AFB plus WLB seems to improve the sensitivity for detection of intraepithelial neoplasia. However, both techniques are similar for detecting invasive lung cancer.^{217,218}

The low specificity of AFB, the lack of evidence for a decrease in disease-specific mortality, and the lack of cost analyses are some of the drawbacks of this technique.²¹⁶ Therefore AFB is not yet considered a screening tool for lung cancer and is primarily being used as a research tool^{213,216} (Fig. 22-13).

NARROW-BAND IMAGING

Visualizing the vascular pattern of the bronchial epithelial surface promises to advance the understanding of angiogenesis in the early phases of carcinogenesis of lung tissue and to advance the diagnosis of premalignant lesions. *Narrow-band imaging* (NBI) is a new, alternative light-wavelength capture system that can be used to detect the altered blood vessel morphology of bronchial dysplasia. Wavelengths of light in the visible spectrum (400 to 700 nm) are filtered to narrow the wavelength to bands in the blue and green spectrum (415 and 540 nm), coinciding with the peak absorption spectrum of oxyhemoglobin and thereby enhancing detection of blood vessels. It may be helpful to detect severely dysplastic lesions; it is estimated that invasive carcinoma will develop in 40% to 83% of patients with severely dysplastic lesions.^{219,220} NBI in combination with high-magnification bronchoscopy can be useful in characterizing capillary loop patterns of dysplastic airway lesions.^{221,222}

NBI may be more specific than AFB for detecting dysplasia when used as an adjunct to AFB to evaluate the vascular

Figure 22-13 False-positive autofluorescence bronchoscopy image in patient with recurrent respiratory papillomatosis involving the trachea. All endobronchial biopsy specimens from the suspicious areas were negative for malignancy.

patterns visualized on areas with abnormal autofluorescence.²⁰³ When NBI is used with WLB, detection of bronchial dysplasia is significantly improved compared with WLB alone. At the same time, NBI requires closer examination both as a stand-alone technology and in comparison with other imaging strategies, including AFB, in the setting of clinical trials.²²³

Because both AFB and NBI are “technologies in search of an indication,” they remain largely research tools and should not be routinely performed outside well-designed clinical trials or special clinical circumstances.^{216,223} In one study, high-magnification bronchovideoscopy combined with NBI was found useful in the detection of capillary blood vessels in angiogenic squamous dysplasia at sites of abnormal fluorescence. Such combined approaches may enable the discrimination between angiogenic squamous dysplasia and other preinvasive bronchial lesions.²²¹

Key Points

- Since its introduction in 1966, flexible bronchoscopy has replaced rigid bronchoscopy for most diagnostic and therapeutic indications; rigid bronchoscopy has a continued role for a few indications such as massive hemoptysis and removal of large foreign bodies, especially in the pediatric population.
- Bronchoalveolar lavage, which samples the distal air spaces, can diagnose several diseases that involve the air spaces, including opportunistic infections, eosinophilic pneumonia, and pulmonary alveolar proteinosis.
- *Transbronchial biopsy* (TBB) has value in the diagnosis of infiltrative diffuse pulmonary diseases. With the advent of novel guidance techniques, such as

electromagnetic navigation, TBB may become accurate at sampling distal focal lesions.

- **Endobronchial ultrasonography (EBUS)** represents a major advance in diagnostic bronchoscopy, allowing ultrasound-guided biopsies from beyond the confines of the tracheobronchial tree. Its major indication today is the sampling of lymph nodes to assess the tumor-node-metastasis staging of non-small cell lung cancer.
- The combination of EBUS and endoscopic ultrasonography is as accurate as mediastinoscopy in the staging of non-small cell lung cancer.
- Advances in confocal bronchoscopy, autofluorescence bronchoscopy, and narrow-band imaging may prove valuable in detecting early malignant lesions of the lung parenchyma and large airways in the future; yet, for now, they remain research tools.

INTRODUCTION AND HISTORICAL BACKGROUND

Gustav Killian performed the first rigid bronchoscopy in 1897 to extract a piece of a pork bone from the right main bronchus.¹ This innovation resulted in a dramatic decrease in the mortality from aspiration pneumonia. In 1966, the flexible bronchoscope was introduced into clinical practice by Shigeto Ikeda.² Currently, the majority of pulmonologists are trained in *flexible bronchoscopy* (FB), whereas only a minority have been trained in rigid bronchoscopy.^{3,4} With the advent of formalized fellowship training programs in interventional pulmonology, training in rigid bronchoscopy is making a comeback and is an extremely valuable instrument in the management of central airway obstruction⁵ (Video 23-1). Whereas FB remains invaluable for the diagnosis of lung masses, parenchymal disease, and mediastinal/hilar adenopathy, the rigid bronchoscope offers the ability to provide an airway allowing oxygenation and ventilation, as well as the passage of large-bore suction catheters and a variety of tools that can aid in the destruction and excision of tumor. Additionally, silicone stents can be placed only via the rigid bronchoscope, thus allowing the physician to place the “best” stent in a selected patient as opposed to being limited to stents that can be placed solely via FB.

THERAPEUTIC BRONCHOSCOPY

Central airway obstruction, from both malignant and non-malignant causes (Table 23-1), is associated with significant morbidity and mortality and often presents a great challenge to physicians. It is estimated that 20% to 30% of patients with lung cancer will develop complications associated with airway obstruction, and the incidence of nonmalignant causes such as postintubation/posttracheostomy stenosis is likely to increase due to the increasing use of artificial airways in an ever-aging population.⁶

It should be noted that designing large randomized trials to investigate comparative efficacy is extremely difficult in patients with central airway obstruction. Limitations

include selecting patients with comparable disease and comorbidities, as well as the fact that many of these patients present in respiratory distress. Double blinding is also clearly impossible. Therefore the literature supporting therapeutic bronchoscopy is primarily based on large case series and retrospective analyses. That being said, the impact of therapeutic bronchoscopy on quality and length of life is impressive.⁷⁻¹⁰ Therapeutic bronchoscopy has also been associated with immediate reductions in the level of care required for patients with acute respiratory failure from central airway obstruction.¹¹

Training in advanced diagnostic and therapeutic bronchoscopy tends to be limited and is more common in centers that have dedicated interventional pulmonology training programs.¹² Over the last several years, dedicated training in interventional pulmonology has become more popular, with 26 dedicated programs currently available in the United States (www.aabronchology.org) and the development of standardized curricula and in-service examinations.^{5,13} The first board examination for IP was administered in 2013.

Even with the recent increase in training in rigid bronchoscopy, the flexible bronchoscope remains an essential tool in therapeutic bronchoscopy. It is used in almost every rigid bronchoscopic procedure and, when rigid bronchoscopy is not available, can also be used as the only bronchoscope for foreign body removal, tumor excision/tumor destruction, and balloon dilation. There are several therapeutic techniques, each with its own associated risks and benefits, advantages and disadvantages (Table 23-2). Because comparative data are lacking, the technique of choice often depends on equipment availability and the bronchoscopist's expertise. Two of the most important considerations in the care of patients with central airway obstruction is assessing the stability of the patient for the planned procedure and having a realistic understanding of the local resources and skill set. Clearly, all efforts should be made to ensure that a patient with a relatively stable airway does not develop an unstable airway during the procedure because these patients can deteriorate quickly. These patients are often best cared for in a multidisciplinary approach in “centers of excellence” that routinely evaluate and manage such problems.⁶

Table 23-1 Causes of Central Airway Obstruction

Nonmalignant	Malignant
Vascular	Primary airway tumors
Sling	Bronchogenic
Cartilage	Mucoepidermoid
Relapsing polychondritis	Adenoid cystic
Lymphadenopathy	Carcinoid
Infectious (e.g., histoplasmosis, tuberculosis)	Tumors metastatic to the airway
Sarcoidosis	Bronchogenic
Granulation tissue associated with:	Renal cell
Artificial airways	Breast
Airway stents	Melanoma
Aspirated foreign bodies	Thyroid
Surgical anastomosis	Colon
Inflammatory lesions	Esophageal carcinoma
Granulomatosis with polyangiitis (Wegener granulomatosis)	Lymphadenopathy from any malignancy
Amyloidosis	Mediastinal tumors
Papillomatosis	Thyroid
Tracheobronchomalacia	Thymus
Other:	Germ cell
Goiter	Lymphoma
Secretions/blood clot	

EVALUATION AND MANAGEMENT OF CENTRAL AIRWAY OBSTRUCTION

FOREIGN BODY REMOVAL

Indications

Foreign body aspiration is one of the most common indications for therapeutic bronchoscopy. There is a bimodal incidence of airway aspiration, peaking in children 1 to 2 years old and in adults older than 70. Risk factors for aspiration in adults include alcohol intoxication, sedative and hypnotic drug use, poor dentition, senility, seizure, trauma, swallowing impairment, parkinsonism, and general anesthesia. In adults, foreign bodies are most commonly found in the right-sided airways but, in children, are found equally in the left and right owing to the equal size and angulation of the main bronchi. Because a history of aspiration is obtained in less than 50% of patients, and visible foreign bodies can be identified on chest radiography in less than 10% of cases, a high index of suspicion is required.¹⁴⁻¹⁷

Contraindications, Procedure, Results, and Complications

All contraindications that apply to routine FB also apply to the removal of a foreign body. Lack of experience and lack of availability of all necessary endobronchial accessories are the more important considerations. Removal of a foreign body using FB should be attempted only by or under the supervision of an expert bronchoscopist. The removal

Table 23-2 Advantages and Disadvantages of Therapeutic Modalities

Modality	Time to Achieve Results	Advantages	Disadvantages	Cautions
Electrocautery	Immediate	Inexpensive Multiple accessories	Often need to couple with mechanical débridement	Need to deactivate pacemaker/AICD Keep $\text{FI}_2 < 0.4$
Argon plasma coagulation	Immediate	Inexpensive Can treat at an angle to electrode	Risk for gas embolization with higher flow rates Often need to couple with mechanical débridement	Need to deactivate pacemaker/AICD Depth of penetration 2-3 mm Keep $\text{FI}_2 < 0.4$
Laser	Immediate	Extensive data supporting its use	Need laser safety precautions	Depth of penetration up to 10 mm Keep $\text{FI}_2 < 0.4$
Stent	Immediate	Only bronchoscopic modality for extrinsic compression	All stents have associated complications of granulation tissue formation, infection, and migration	Metallic stents should be used with caution in patients with nonmalignant disease
Microdébrider	Immediate	Can use in high- FI_2 environments	May need additional tools to provide hemostasis	Cannot reach distal airways
Cryotherapy	48-72 hr	Normal airway is cryoresistant Can use in high- FI_2 environments	Delayed maximal effect, requiring "cleanout" bronchoscopy	Cryo-adhesion can remove organic foreign bodies
Photodynamic therapy	48-72 hr	Can destroy submucosal tumor Can use in high- FI_2 environments	Delayed maximal effect, requiring "cleanout" bronchoscopy Systemic photosensitivity Need laser safety precautions	Swelling of tumor can cause obstruction
Brachytherapy	Delayed: days—weeks	Can destroy submucosal tumor	Coordination with radiation oncology	Radiation bronchitis Risk for erosion into vessels Swelling of tumor can cause obstruction

AICD, automatic internal cardiac defibrillator.

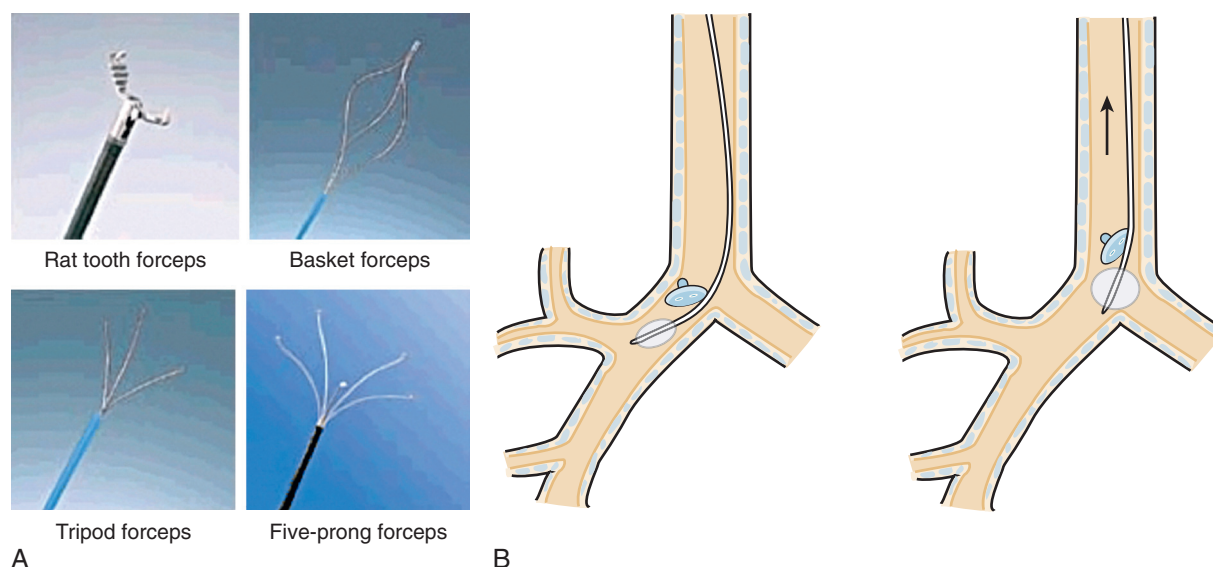

Figure 23-1 **A**, Examples of foreign body retrieval tools: rat tooth forceps, basket forceps, tripod forceps, five-prong forceps. **B**, Schematic representation of the use of a balloon catheter for dislodging a foreign body by a retrograde pull. (**B**, Courtesy Dr. Eric Folch.)

of foreign bodies can be performed successfully with either the flexible or rigid bronchoscope. Flexible bronchoscopy is successful in 86% to 91% of cases, whereas rigid bronchoscopy is successful in 99.9%.^{15,16,18-24} If available, rigid bronchoscopy should be used in all cases of acute respiratory distress caused by foreign body aspiration given the near 100% success rate and the speed at which the procedure can be performed. The benefits of FB include its widespread availability and its lack of a requirement for general anesthesia.

Foreign body removal using FB is carried out in stages: first, dislodging the foreign body; then, grasping or securing the object; and finally, removing it along with the flexible bronchoscope as a single unit. A variety of ancillary accessories (forceps, grasping claws, snares, baskets, and magnets) are available for foreign body extraction (Fig. 23-1). A cryoprobe passed through the flexible bronchoscope can be especially useful for the removal of blood clots, mucous plugs, and organic material, because the extreme cold can cause immediate and strong adherence (“cryoadherence”) to the biologic materials. Once the object is grasped and secured, care must be taken to avoid losing it in the subglottic area or at the level of the vocal cords. If necessary, the patient can also be asked to cough to expel the foreign body once it has been brought into the mid-upper trachea.

Serious complications can accompany removal of a foreign body, including central airway obstruction, hypoxemia, bronchospasm, and bleeding. Objects can also migrate, and their fragments can impact in distal airways.

ELECTROCAUTERY

Endobronchial electrocautery is the application of heat produced by high-frequency electrical current to treat tumor tissue. It involves the use of special accessories such as blunt probes, hot forceps, knives, and snares introduced through a bronchoscope. The probe functions as an active electrode that focuses heat at the point of contact, leading to tissue

coagulation or vaporization. The electrical current can also cut or combine cutting with coagulation. The degree of tissue destruction depends on the power used, duration of contact, surface area of contact, and water content of the tissue. Use of the snare device is especially suited to the removal of a pedunculated airway lesion because cauterization of the stalk can allow removal of the majority of the tumor for pathologic review (Video 23-2).

To avoid endobronchial ignition, the *fractional concentration of oxygen in inspired gas* (FIO₂) should be kept below 0.4. Insulated bronchoscopes, compatible with electrocautery, are used to prevent leakage of electrical current, avoiding burns or electrical shock to the patient and the bronchoscopist.

Indications and Contraindications

Electrocautery is used for either coagulation or vaporization of malignant or nonmalignant disease within the airways and has been shown to be potentially curative in patients with carcinoma in situ. Coagulation is achieved by gently touching the tumor tissue and applying 1- to 2-second bursts of 20- to 40-W energy until blanching or destruction of the mucosa becomes apparent. Additional contact time can result in vaporization of the tissue as desired. The tumor area should be kept free of blood or mucus by continuous suctioning, or the electrical current will be dissipated through these liquids. The coagulated tissue can then be removed using biopsy forceps or suction. The use of electrocautery is contraindicated in patients with pacemakers and/or defibrillators to avoid electrical interference with these devices.²⁵

Results and Complications

Electrocautery has been used effectively and safely as an ablative modality in both malignant and nonmalignant airway obstruction. In several studies, electrocautery has been shown to achieve luminal patency and symptomatic improvement at rates similar to *laser* (light amplification by stimulated emission of radiation) and other ablative airway

modalities.²⁶⁻³⁰ Moreover, electrocautery is a cost-effective bronchoscopic intervention due to the low cost of the machine and the reusable nature of its accessories.²⁶ In a selected group of patients with small, polypoid endobronchial lesions, Coulter and Mehta³¹ showed that electrocautery had a high success rate (89%) under local anesthesia, thereby eliminating the need for the more costly laser therapy. Complications are rare in experienced hands: the most common ones are bleeding (2% to 5%), endobronchial fire in a high-FiO₂ environment, and electrical shock to the operator should the cautery probe touch an ungrounded bronchoscope.

ARGON PLASMA COAGULATION

Argon plasma coagulation (APC) is a noncontact form of electrocautery that uses ionized argon gas (plasma) to conduct electrical current from the probe to the tissue. Because positively charged argon gas flows toward the negatively charged tissue, treatment can be directed in an axial or tangential fashion (Fig. 23-2A). As the tissue becomes desiccated, it offers more resistance to the electrical current, limiting its penetration to approximately 2 to 3 mm.^{25,26} APC probes can be passed via a rigid or flexible bronchoscope.

A

B

Figure 23-2 **A**, Schematic presentation of argon plasma coagulation. Arrow shows the tungsten carbide electrode. Positively charged argon gas automatically flows radially to the negatively charged bleeding tissue. **B**, Damage to the tip of the bronchoscope caused during argon plasma coagulation by having the catheter too close to the tip of the bronchoscope during activation. Note the charred tip along with the frayed rubber sheath. (A, Courtesy Dr. Eric Folch.)

Indications and Contraindications

APC is frequently used for palliation of malignant airway obstruction as part of multimodality therapy, including mechanical débridement; mechanical débridement is needed to remove the cauterized tissue because, unlike laser, APC and other forms of electrocautery do not vaporize tissue. APC is also extremely useful for control of bleeding in the central airways and has been used for the treatment of excess granulation tissue (including stent-related granuloma), postinfectious airway stenosis, and endobronchial papillomatosis (Video 23-3).^{25,26} The most important advantages of this technique are the ability to treat lesions at sharp angles from the tip of the electrode, to treat lesions in close proximity to airway stents, and to achieve superior hemostasis. Its major limitation is the depth of penetration of less than 3 mm; however, this also may reduce the risk for airway perforation. Its only absolute contraindication is the presence of a pacemaker or implantable defibrillator susceptible to electrical interference. As with electrocautery and laser use in the airway, APC requires that the FiO₂ be < 0.4.

Results and Complications

In properly selected cases, APC provides symptomatic relief in almost 90% of patients. It is also portable, less expensive than laser, and typically available in most operating rooms (though bronchoscopic fibers may need to be purchased). Potential complications include gas embolization,³² airway fire, postprocedure stenosis, and injury to deeper structures or to the flexible bronchoscope (see Fig. 23-2B). The observed mortality and overall complication rates are 0.4% and 3.7% of cases, respectively.^{33,34}

LASER PHOTORESECTION

Laser light has three unique characteristics—monochromaticity, coherence, and collimation—that permit controlled delivery of a well-defined energy. Laser light causes thermal, photodynamic, and electromagnetic changes in living tissue. Laser energy can cut, coagulate, or vaporize endobronchial lesions in a predictable manner, depending on the wavelength used. Although many types of laser systems exist, the *neodymium:yttrium-aluminum-garnet* (Nd:YAG) and *neodymium:yttrium-aluminum-perovskite* (Nd:YAP) lasers are most commonly used in the airways because of their ability to coagulate and vaporize tissue, with a depth of penetration of 5 to 10 mm.²⁶ Though the carbon dioxide laser provides minimal hemostasis, it is extremely precise (depth of penetration of <1 mm). Such precision can permit fine procedures such as those needed to incise weblike stenoses or to remove granulation tissue surrounding airway stents.

Indications

The main indications for *laser photoresection* (LPR) are relief of central airway obstruction from exophytic obstructive neoplasms and from tracheal stenosis (Video 23-4). An ideal lesion for the LPR is an endobronchial tumor that arises from a single wall of a central airway and has a visible distal lumen, with a duration of lung collapse of less than 4 to 6 weeks. LPR can be performed using either a rigid or

flexible bronchoscope. The end results and the complication rates are similar with both types of instruments. The selection of the scope mainly depends upon personal preference, availability of the instruments, and training. Bronchoscopists proficient in rigid bronchoscopy prefer to use the rigid scope because of the ease of mechanical debulking and superior suction capabilities.

Contraindications

Lesions not amenable to LPR are extrinsic or submucosal, primarily involving lobar or segmental bronchi, and those for which the operator is unable to identify a patent airway distal to the obstruction. As with other forms of heat therapy, laser is contraindicated in patients with a high oxygen requirement.²⁶

Results and Complications

LPR can restore airway patency with immediate symptomatic improvement in 93% of cases (Fig. 23-3).^{26,35} It can be combined with other techniques such as APC and stent placement to achieve full patency of major airways. This technique palliates symptoms of cough, dyspnea, and hemoptysis along with documented benefits in radio-

graphic, spirometric, and quality of life parameters. Studies have shown a small survival benefit when emergent LPR is compared with emergent radiotherapy. LPR is associated with the following complications (range, 0% to 2.2%): exsanguination (2%), endobronchial ignition, pneumothorax or barotrauma, bronchopleural or bronchoesophageal fistula, and hypoxemia.³⁶ Extensive knowledge of the anatomy of the tracheobronchial tree is mandatory before performing the procedure. Accumulation of blood and secretions can lead to rapid desaturation. Tracheobronchial tree perforation can be fatal owing to the close proximity of the great vessels. While performing the procedure, one must take precautions to avoid airway fires, activating the laser only when the FiO_2 is < 0.4 . Laser safety precautions for the bronchoscopist and operating room personnel are also required.³⁶

STENT PLACEMENT

Stents are devices used for the internal splinting of luminal structures. The first stents that were used in the trachea were the T tubes developed by Montgomery.³⁷ Though they require a tracheostomy for their placement, these silicone

stents are still widely used, primarily in patients with high tracheal stenosis and/or malacia. Westaby and colleagues modified this stent and designed a T-Y prosthesis, which enabled splinting of the distal trachea and carina. Dumon³⁸ later developed the first stents that could be inserted through a bronchoscope without a tracheostomy. Over the years, several other stents have been developed, including “dynamic” stents made to mimic the airway with a “posterior longitudinal membrane,” stents made of steel or nitinol (a nickel-titanium alloy), as well as newly developed (though not commercially available) bioabsorbable and drug-eluting varieties (Fig. 23-4).³⁹ Unfortunately, there is no perfect stent. The ideal stent would be easy to insert and remove, strong enough to support the airway yet flexible enough to mimic normal airway physiology and promote secretion clearance, biologically inert to minimize the formation of granulation tissue, and available in a variety of sizes and shapes. Whereas self-expanding metallic stents can be placed with flexible bronchoscopy, silicone stents require rigid bronchoscopy. Many bronchoscopists who perform rigid bronchoscopy feel it is significantly easier to place metallic stents via the rigid bronchoscope due to the fact that patients are under general anesthesia and the larger rigid forceps allow for easier stent manipulation. All currently available stents have their own advantages and disadvantages, and thus it is most important to select the best stent for the individual patient. This requires the bronchoscopist to be familiar with and able to place a variety of stents.

Indications and Contraindications

Indications for airway stent placement include (1) counteracting extrinsic compression from tumors or lymph nodes (Video 23-5); (2) preventing regrowth of intraluminal tumor that will compromise an airway, (3) maintaining airway patency in patients with significant and symptomatic malacia, and (4) sealing malignant fistulas.²⁶ Because one of the major complications of metallic stents is epithelialization, which makes removal extremely difficult, the U.S. Food and Drug Administration has issued a warning against the use of metallic stents in patients with benign conditions until all therapeutic options, including use of silicone stent and surgery, have been explored. Though many of the other modalities described in this chapter can be used to treat patients with intraluminal or transmural

disease, airway stents are the only bronchoscopic modality that can treat extrinsic airway compression.

Results and Complications

Airway stenting has been associated with improved quality and length of life in patients with malignant airway obstruction,^{26,40,41} improved quality of life in patients with tracheobronchomalacia,⁴² an increased ability to be liberated from the ventilator, even in patients with nonmalignant disease,⁴³ and improved lung function and pulmonary infection rates in patients with airway stenosis following lung transplantation.⁴⁴

Retained secretions, bacterial colonization, migration, stent fractures, and development of granulation tissue are frequent complications, and all can be seen with any type of stent. Silicone stents tend to have a higher incidence of migration, whereas covered metallic stents are more prone to infection.⁴⁵ Silicone stents and the presence of lower respiratory tract infections were also found to increase the risk for granulation tissue formation. Though typically requiring rigid bronchoscopy, removal of silicone stents is a relatively easy procedure. Removal of metallic stents on the other hand, especially the uncovered/partially covered varieties, can be extremely difficult and associated with significant complications and cost.^{46,47} As such, it is our practice to perform surveillance bronchoscopy to assess for stent-related complications at approximately 6 weeks following stent placement because the complications, if present, are often easier to manage earlier rather than later, once the patient develops symptoms.

MICRODÉBRIDER

The microdébrider is a form of “powered instrumentation” that uses a spinning blade contained within a rigid suction catheter to cut tissue while providing suction to remove blood and tumor/granulation tissue^{48,49} (Video 23-6). We generally use a 45-cm-long, 4-mm-wide angle-tip blade, allowing it to reach lesions in the trachea, main-stem bronchi, and bronchus intermedius. Advantages of the microdébrider are that it can be used in high-FiO₂ environments, and, because it does not vaporize tissue, a specimen trap can be connected in line so that tissue can undergo pathologic analysis. The continuous suction also provides a clean operating environment. Because the microdébrider

does not use any thermal energy, it is often necessary to use additional modalities such as APC to achieve complete hemostasis. When used by skilled operators, adverse events are rare but can include airway perforation and bleeding.

CRYOTHERAPY

Cryotherapy relies on repeated freeze-thaw cycles to cause tissue damage. Maximal cellular damage results from rapid and deep cooling and a relatively slow thaw. The Joule-Thompson effect describes the drop in temperature that develops as a gas expands from a high-pressure to a low-pressure environment. The most commonly used cooling agents (cryogenes) available are nitrous oxide and carbon dioxide. The cryoprobe can be used through rigid or flexible bronchoscopes. When nitrous oxide is used, the temperature at the tip of the probe falls to -89°C within several seconds. The temperature increases approximately 10°C per mm from the tip (“warming effect”), so the effective killing zone is approximately 5 to 8 mm. Because freezing and recrystallization depend on cellular water content, cartilage and fibrous tissue are relatively cryoresistant, making it more difficult to damage the normal airway with this therapy than with other forms of thermal energy. Repeated cycles of freezing and thawing are applied to the endobronchial tissue in a contiguous fashion to cover the entire surface of the lesion. Tissue necrosis and sloughing takes place within 24 to 48 hours, and a “cleanup” bronchoscopy is usually required to remove necrotic tissue. This delayed tissue effect is one of the shortcomings of cryotherapy.⁵⁰

Indications and Contraindications

 Cryotherapy has been used for the destruction of endobronchial lesions when immediate results are not mandatory and “hot” therapies are contraindicated (Video 23-7). For example, cryotherapy is ideal for treating stent-related granulomas when the stent is made of a flammable material.^{26,50} Cryotherapy can be used with excellent results in removing organic foreign objects, blood clots, and mucous plugs by cryoadhesion, as described earlier. Advantages of cryotherapy include its ability to be used in a high-oxygen environment and its limited bronchial wall damage.⁵⁰ A newer form of cryotherapy, cryoextraction, has also been described recently, in which tumor in the central airways is frozen to the cryoprobe and removed en bloc with the bronchoscope in a similar manner as removing a foreign body.⁵¹

Results and Complications

In most cases, cryotherapy offers a safe and inexpensive alternative for ablation of endobronchial tumor, with success rates up to 80%.^{52,53} As mentioned, tumor sloughing requiring a repeat bronchoscopy and delayed maximal effect are the two major downsides of using cryotherapy for tumor excision. Moderate bleeding, mediastinitis, and fistula formation following cryotherapy have also been encountered in few cases, though the risk for bleeding is likely less than with other therapies due to the vasoconstrictive and platelet-aggregating properties of cryotherapy.⁵⁰ Likewise, the risk for airway fire is nonexistent. It should be noted that the risk for bleeding with cryoextraction may be higher than when cryotherapy is used for tumor destruction.

PHOTODYNAMIC THERAPY

Photodynamic therapy (PDT) refers to a process by which a photosensitizing drug is activated by a nonthermal laser light to induce a phototoxic reaction leading to cell death. PDT is a three-step process. On day 1, a photosensitizing agent such as porfimer sodium) is administered intravenously. Forty-eight hours after injection, the drug is preferentially retained by tumor cells and cleared from most healthy tissues, and the tumor is then exposed to a nonthermal laser light introduced via a flexible bronchoscope. Exposure of the drug to light of 630 nm results in a photochemical reaction, including generation of oxygen radical species, direct damage to cells and organelles, indirect ischemic effects, apoptosis, and inflammatory effects. One to two days later, a cleanup bronchoscopy is then necessary to remove the devitalized tissue, which is difficult to expectorate and can cause complications such as postobstructive pneumonia, respiratory distress, or respiratory failure.²⁶

Indications and Contraindications

PDT is indicated for the palliation of advanced non-small cell lung cancer obstructing the tracheobronchial tree and appears to be effective for superficial as well as submucosal disease. Curative treatment for early lung cancer/carcinoma in situ is another indication for PDT. Occasionally it is also used preoperatively to reduce the extent of surgical resection by rendering the line of resection free of disease.

Owing to its delayed effect and to the possible swelling of the lesion following the therapy, PDT is relatively contraindicated for treatment of tracheal and carinal lesions or lesions in postpneumonectomy patients (i.e., lesions for which any swelling might precipitate total lung obstruction). PDT is also contraindicated if the tumor invades vascular structures or if there is a history of porphyria and/or porphyrin hypersensitivity.

Results and Complications

PDT has been used to treat advanced lung cancer,⁵⁴ to treat multiple malignancies alone or in combination with surgery,⁵⁵ and to pretreat to reduce the extent of the surgical resection.⁵⁶ In superficial tumors a complete remission rate between 64% and 98% with PDT has been described, and balloon-sheath endobronchial ultrasonography can be invaluable in determining lack of transmural spread.^{54,55,57}

Compared to other therapies, PDT is not immediately effective and therefore should not be used for acute central airway obstruction. Additionally, cleanup bronchoscopy is required, and the induced systemic photosensitivity mandates that the patient avoid sunlight for 4 to 6 weeks, a potentially major drawback for those with limited life expectancy.⁵⁸ The most common complications include skin photosensitivity, local airway edema, strictures, hemorrhage, and fistula formation.²⁶

BRACHYTHERAPY

Brachytherapy refers to a technique in which the radiation source is placed within or in close proximity to the target to deliver the maximum dose of radiation to the tumor while sparing the normal surrounding tissues. The radiation dose

to the surrounding tissue is dictated by the inverse square law, according to which the radiation dose decreases as a function of the inverse square of the distance from the center of the source. Thus this mode of radiation therapy allows the tumor to receive significantly higher radiation doses than the surrounding healthy tissues such as lung parenchyma and mediastinal vasculature.

For central airway lesions, a polyethylene catheter is placed adjacent to the lesion via FB and its position verified by fluoroscopy. The catheter is then loaded with the radioactive source. Low-dose-rate, intermediate dose rate, and high-dose-rate treatments imply a dose of less than 2 Gy/hr, 2 to 12 Gy/hr, and greater than 12 Gy/hr, respectively, to a target at a distance of 10 mm. High-dose-rate brachytherapy, which uses Iridium-191 as the radiation source, is the most common form of brachytherapy and is typically applied in three treatment sessions over a week in the outpatient setting.⁵⁹ Brachytherapy requires close collaboration between the bronchoscopist and the radiation oncologist. The role of the bronchoscopist is to identify appropriate patients and place a catheter into the tracheobronchial tree, whereas the radiation oncologist calculates the radiation dose and guides the actual delivery of radiation to the tumor.

Indications

Brachytherapy is most useful for endobronchial tumors with a component of submucosal/peribronchial disease. Brachytherapy is also useful for recurrent tumors following maximally tolerated external beam radiation. The primary goal of brachytherapy is palliation of tumor symptoms such as cough, dyspnea, and hemoptysis. Because it requires up to 3 weeks for the tumor to regress, brachytherapy is not suitable for immediate relief of obstructive symptoms.⁵⁹ Brachytherapy is a therapeutic option for occult early-stage central lung cancers when surgery cannot be performed. Brachytherapy has also been used in management of excessive granulation tissue at the site of anastomosis in lung transplant recipients.⁶⁰

Contraindications

A few absolute contraindications for endobronchial brachytherapy exist, such as known fistulas involving the airways. To avoid life-threatening complications, one should exclude tumors directly involving the major vessels. Patients with endotracheal carcinoma causing high-grade obstruction should not be treated with brachytherapy because of the delayed effects and potential postradiation edema that could lead to total airway obstruction.

Results and Complications

The studies that combined external radiation with brachytherapy showed that, even if quick airway response was gained, there was no survival benefit; thus its role is mainly for palliation. Brachytherapy is reported to improve cough in 20% to 70%, dyspnea in 25% to 80%, and hemoptysis in 70% to 90% of patients. For patients who have not yet received radiation, external beam radiation therapy offers improved duration of response and survival compared with brachytherapy alone; thus external beam radiation therapy should be selected as first-line therapy instead of brachytherapy for lung cancer patients with central lesions.⁶¹ In patients with inoperable early-stage cancer of the central

airways, brachytherapy has been reported to produce a complete endoscopic response in up to 60% to 90% with 5-year survival rates of 30% to 80%.^{59,62,63}

Complications include respiratory compromise, massive hemoptysis, fistula formation, radiation bronchitis, and airway stenosis. Fatal hemoptysis has been reported in up to 5% to 10% of patients. The risk for late exsanguination has been found to be highest in patients receiving brachytherapy to the right upper lobe, owing to its close proximity to the pulmonary artery.^{59,62}

EMERGING TECHNOLOGIES

BRONCHOSCOPIC LUNG VOLUME REDUCTION

To date the only options for patients with advanced emphysema are lung volume-reduction surgery and lung transplantation. The National Emphysema Treatment Trial demonstrated that, in patients with heterogeneous emphysema with upper lobe predominance and low exercise capacity, lung volume-reduction surgery significantly improves lung function, exercise tolerance, quality of life, and survival.⁶⁴ Unfortunately, the associated morbidity and mortality of the procedure have limited its widespread application.

Indications and Contraindications

Endobronchial treatment of severe emphysema has been studied for over a decade and has been approved in several countries around the world. Incidentally, it still remains a matter of research in the United States at the time of writing this chapter. Various devices and chemical agents have been used via the endobronchial route to reduce lung volumes in a relatively noninvasive fashion.⁶⁵⁻⁷⁰ The majority of studies have focused on patients with heterogeneous (i.e., upper lobe predominant) emphysema, though some have also investigated patients with homogenous disease. Because all of these techniques are relatively new, the ideal patient population for each specific approach will need to be defined. The following section provides a brief review of current knowledge related to concepts of bronchoscopic lung volume reduction.

Endobronchial Valves

Endobronchial valves are one-way valves designed to allow air to exit the targeted lung segment without allowing reentry of the inspired air, thus leading to deflation of the emphysematous portion of the lung and volume reduction. Two different types of valves, the Zephyr (Pulmonx Corporation) and the IBV (Olympus Corporation) have been evaluated. The Endobronchial Valve for Emphysema Palliation Trial (VENT), a randomized, prospective, multicenter study, examined the safety and efficacy of the Zephyr endobronchial valve in comparison to optimal medical care in patients with advanced heterogeneous emphysema.⁶⁶ Primary efficacy end points were percent changes in FEV₁ and 6-minute walk test. Though there were modest improvements in these end points, they did not reach clinical significance, and the U.S. Food and Drug Administration did not approve the valve for use in the United States. Optimal valve placement to achieve total lobar exclusion and the presence of a complete fissure separating the treated lobe were two

determinants of significant improvement. A bronchoscopic system (Chartis; Pulmonx Corporation) to detect collateral ventilation has been developed that has an effectiveness of approximately 75% in predicting clinical improvement after lobar occlusion with valves.⁷⁰ Studies of the IBV in patients with upper lobe predominant emphysema also reported improvements in health-related quality of life but did not find improvement in pulmonary function or exercise capacity.⁶⁹

Bronchial Lung Volume-Reduction Coils

The bronchial lung volume-reduction coil (PneumRx) is made of nitinol wires that, when deployed by advancing into the bronchus via the bronchoscope, retract and fold the parenchyma, thus reducing lung volume in abnormal areas with the goal of restoring elasticity to the normal areas. The virtue of this approach is that the presence of collateral ventilation does not affect its efficacy. Preliminary studies using lung volume-reduction coils have been shown to improve quality of life, pulmonary function, and the 6-minute walk test.⁷¹

Biologic Sealant

Bronchoscopic lung volume reduction using direct application of a biologic sealant to collapse areas of emphysematous lung has been reported. Initial tests of a synthetic polymeric foam sealant (emphysematous lung sealant, AeriSeal) have shown improvements in pulmonary function, exercise capacity, and quality of life.⁶⁸ It should be noted that fissure integrity may not be as important with this method of achieving bronchoscopic lung volume reduction.⁷²

Bronchoscopic Thermal Vapor Ablation

Bronchoscopic thermal vapor ablation involves delivery of a precise amount of steam water vapor at a precise temperature directly into the targeted lung segments via a specialized catheter. The thermal reaction produces a localized inflammatory response leading to fibrosis and atelectasis. This results in complete and permanent lung volume reduction. Improvements in pulmonary function and quality of life have been reported with this technique in preliminary studies.⁷³ As with the reduction coils and biologic sealants, a potential advantage of bronchoscopic thermal vapor ablation is that success is independent of the presence or absence of collateral ventilation.⁷⁴

Complications

Because these procedures are performed in patients with severe underlying emphysema, complications can be expected. The more common complications include transient reductions in lung function, flares of bronchitis or pneumonia, and pneumothorax. Whereas placement of valves is reversible, the placement of coils, instillation of sealant, and ablation via bronchoscopic thermal vapor are irreversible procedures.

BRONCHIAL THERMOPLASTY

Bronchial thermoplasty (BT) is a novel bronchoscopic treatment for patients with severe asthma aiming to reduce the airway smooth muscle mass, therefore diminishing bronchial constriction and improving asthma symptoms.⁷⁵ This

A

B

Figure 23-5 A, The radiofrequency ablation catheter used for bronchial thermoplasty. B, The disposable catheter contains a four-electrode basket that delivers controlled heat to the airways.

is accomplished by delivering controlled heat to the airway walls via a radiofrequency electrical generator and a disposable catheter with an expandable four-electrode basket at its distal tip (Fig. 23-5). BT is performed in three bronchoscopy sessions, 2 to 3 weeks apart. The first two sessions treat each lower lobe separately, and the third session treats both upper lobes (the right middle lobe is not treated, because it was not included in recent study protocols). Radiofrequency energy is delivered in a systematic fashion at 5-mm intervals starting from just beyond the endoscopic visual limit to the proximal lobar bronchi.

Indications and Contraindications

BT is indicated in adult patients with severe persistent asthma who remain symptomatic despite maximal medical treatment. Concomitant medical conditions that can contribute to asthma symptoms should be sought and treated before resorting to this treatment. In addition, BT should not be used as a substitute for medication compliance. Contraindications for BT include the presence of an implantable electronic device, severe comorbid conditions that increase the risk of the procedure, and FEV₁ of greater than 65% predicted. In children (age < 18 years), the procedure has not been studied and is not approved.

Results and Complications

In multiple studies performed in patients with asthma of various severity, BT has been shown to reduce asthma exacerbations and improve quality of life. Adverse events were

limited to an increase in asthma exacerbations in the perioperative period.⁷⁶⁻⁸⁰

The definitive study of BT, which led to Food and Drug Administration approval, used a randomized double-blind, sham-controlled design of 288 subjects with severe persistent asthma. Patients receiving BT had improvement in quality of life based on a questionnaire but, most importantly, had a 30% reduction in severe exacerbations, an 80% reduction in emergency department visits, and a decrease in days missed from work or school.⁸⁰ The short-term adverse events included airway inflammation and upper respiratory infections that resolved with conventional treatment. There was a higher rate of hospitalization in the BT group in the postprocedure period. A recent study reported on the 5-year follow-up of 162 patients enrolled in the study just described and demonstrated durability of the benefits of BT and safety up to 5 years.⁸¹

ENDOBONCHIAL VALVE PLACEMENT FOR PROLONGED AIR LEAKS

Prolonged air leaks following thoracic surgery are a common complication, reported in up to 18% of patients undergoing lobectomy or lesser resections, and are associated with prolonged hospitalizations, morbidity, and considerable health care costs.⁸²⁻⁸⁴ The usual management of these patients includes prolonged tube thoracostomy drainage, pleurodesis, or attempts at surgical repair. The IBV (Olympus), initially developed as an approach to achieve bronchoscopic lung volume reduction in patients with emphysema, has received Food and Drug Administration approval as a humanitarian use device for the treatment of prolonged leak following lobectomy, segmentectomy, or lung volume-reduction surgery. The procedure is performed under deep sedation/general anesthesia and begins with selective balloon occlusion of the suspected airways. When the culprit airway is occluded, a significant reduction or cessation of the leak can be visualized in the water-seal chamber of the chest drainage system. A calibrated balloon is used to select the proper-sized valve, which is then placed under bronchoscopic control. It is common that multiple valves are used in each case because many patients have a degree of collateral ventilation. After 6 weeks the valves are removed. IBV use in this patient population has been associated with cessation of the air leak in as little as 1 day following placement and hospital discharge within 3 days in the majority of patients. Though complications can theoretically include postobstructive pneumonia, hypoxemia, and valve migration, these seem to be quite rare. More data are required before the use of endobronchial valves can be recommended for other causes of prolonged air leaks such as in the setting of secondary spontaneous pneumothorax.

Key Points

- Rigid and flexible bronchoscopy are essential tools for the interventional pulmonologist.
- Therapeutic bronchoscopy can improve quality and length of life in patients with central airway obstruction.

- Each therapeutic bronchoscopic modality has its own advantages and disadvantages; it is hoped that, with ongoing research, the best use of these techniques will be determined.
- Patients with central airway obstruction are best served by a multidisciplinary team of an interventional pulmonologist, thoracic surgeon, head and neck surgeon, anesthesiologist, and medical and radiation oncologist.
- Central airway obstruction with tumor can be approached by immediate (e.g., laser, stent) or delayed approaches (e.g., cryotherapy, photodynamic therapy). Techniques with immediate action should be selected when urgent therapy is needed or when any swelling would compromise ventilation.
- The hot techniques (electrocautery, argon plasma coagulation, laser photoresection) have immediate effects but cannot be used in a high-FiO₂ environment because of the risk for fire. For immediate therapy in a high-FiO₂ setting, a stent or microdebrider can be considered.
- Stent placement is the only technique that can treat extrinsic airway compression.
- Lung volume reduction can now be achieved via bronchoscopic techniques, including one-way endobronchial valves; however, these are not yet approved in the United States. One-way valves are reversible and affected by collateral flow; lung volume-reduction coils, biologic sealants, and thermal vapor ablation are irreversible and are useful even in the presence of collateral air ventilation.

**DIFFERENCES BETWEEN
THORACOSCOPY AND VIDEO-
ASSISTED THORACIC SURGERY****INTRODUCTION**

Biopsy procedures play an essential role in the diagnostic evaluation of patients with respiratory diseases. Most of the basic techniques we use today were mainly developed and refined during the 20th century. Recently, significant advances in endoscopic technology have provided sophisticated endoscopic instruments and endoscopic telescopes with extremely high optical resolution and small diameters. In addition, developments in anesthesiology offer a wide range of alternatives, from procedures performed under local anesthesia to selective double-lumen intubation under general anesthesia.

As with all medical procedures, the risk-benefit ratio of more invasive methods has to be considered for each individual patient, weighing the risk for morbidity and mortality against the benefit of obtaining an early diagnosis to guide correct therapy. Usually the more invasive procedures are used if simpler, less invasive methods have failed, if the latter are not very promising for obtaining a reliable diagnosis, or if additional therapeutic options can be combined with the diagnostic approach.

This chapter reviews these more invasive thoracoscopic procedures as performed by pulmonologists. Other biopsy methods, such as bronchoscopic biopsies, thoracentesis, needle biopsy of lung lesions, and closed-needle biopsy of the pleura, are described in other chapters.

**THORACOSCOPY (PLEUROSCOPY/
MEDICAL THORACOSCOPY)****HISTORICAL DEVELOPMENT**

Thoracoscopy was introduced together with laparoscopy in 1910 by Hans-Christian Jacobaeus, who at that time worked as an internist in Stockholm, Sweden. He published his first experiences in a paper entitled "On the Possibility to Use Cystoscopy in the Examination of Serous Cavities."¹ It was recently reported that, as early as 1866, F.R. Cruise in Ireland had possibly been the first to perform a thoracoscopy, examining the pleural space of a girl with empyema through a pleurocutaneous fistula that had developed after spontaneous pleural drainage.² Jacobaeus, in his pioneering

paper,¹ mentions two cases of pleuritis exudativa (tuberculous pleurisy), in which he studied the pleural surfaces after replacing the fluid with air. Although not able to get a clear impression of the pleural changes, he was confident that the method would be successful in the future and might eventually yield prognostic information. Jacobaeus³ himself initiated the therapeutic application of thoracoscopy for lysis of pleural adhesions by means of thoracocautery to facilitate pneumothorax treatment of tuberculosis ("Jacobaeus operation"). During the ensuing 40 years, his technique of using a single entry site for the thoracoscope and another for the electrocautery device under local anesthesia was applied worldwide for this specific therapeutic purpose, until antibiotic therapy of tuberculosis was introduced and made the procedure obsolete.⁴ Between 1950 and 1960, a generation of chest physicians familiar with the therapeutic application of thoracoscopy began to use the technique for biopsy diagnosis of pleural and even pulmonary disease.⁵ Today, thoracoscopy is considered as an integral part of interventional pulmonology.⁶

At the same time, the excellent results of laparoscopic surgery and the tremendous advances in endoscopic technology stimulated many thoracic surgeons almost simultaneously in Europe and the United States to develop minimally invasive techniques, which were termed "therapeutic" or "surgical thoracoscopy," as well as video-controlled or videothoracoscopic surgery, or *video-assisted thoracic surgery* (VATS).⁷⁻¹⁰

To clarify the difference between the two methods, the term *medical thoracoscopy* was introduced.¹¹ This is performed using the Jacobaeus technique under local anesthesia or conscious sedation, via a single or two sites of entry, by the pulmonary physician in an endoscopy suite using nondisposable rigid instruments.¹² Its main indications are the diagnosis and treatment of recurrent pleural exudative effusions and the treatment of spontaneous pneumothorax. However, because the term *thoracoscopy* is used for both the medical and the surgical procedures, a degree of uncertainty has arisen, which may lead to unnecessary surgical interventions for what are, in fact, medical indications. Recently the old term *pleuroscopy*⁴ has been reintroduced mainly for thoracoscopy with the semirigid (semiflexible) instrument called a pleuroscope.

Finally, in some countries, interventional pulmonologists have broadened their field of expertise to include more

elaborate interventions (e.g., sympathectomy, splanchnicectomy, treatment of empyema)¹³⁻¹⁵ and to perform thoracoscopy in the operating theater, under total intravenous anesthesia and spontaneous ventilation (with a laryngeal mask or simple endotracheal tube protecting the airway) or mechanical ventilation.

In fact, the terms *thoracoscopy*, *medical thoracoscopy*, and *pleuroscopy* are used interchangeably in the literature. To avoid confusion, in this chapter we will use the term *thoracoscopy* for the procedure performed by the pulmonologist, and consequently also the terms *thoracoscopist* and *thoracoscope*. For the thoracoscopic procedure performed by a surgeon, we will use the term *VATS*.

In Europe thoracoscopy is part of the training program of pulmonary medicine,¹⁶ and it is becoming more popular in the United States. According to a national survey in 1994, thoracoscopy was used frequently by 5% of all pulmonary physicians.¹⁷ Although newer data are not yet available, the interest in the technique seems to be increasing.¹⁸ However, training is lagging: in an American College of Chest Physicians' survey of U.S. pulmonary/critical care fellowship programs in 2002–2003, only 12% of the directors stated that thoracoscopy was offered in their programs.¹⁹ In the United Kingdom, where thoracoscopy has been underutilized compared with the rest of Europe, there is also growing interest.²⁰⁻²³ The British Thoracic Society published a guideline on thoracoscopy (using local anesthetic) in 2010.²⁴ In this guideline, three levels of competence in thoracoscopy are defined, of which level 1 includes basic diagnostic and therapeutic techniques and level 2 the more advanced techniques, whereas level 3 covers all VATS techniques (e.g., lung resection) and is the province of the thoracic surgeon.²⁵

Meanwhile, the technique has been introduced successfully in many Asian countries and in other parts of the world, particularly with the introduction of the semirigid (semiflexible) thoracoscope, called a *pleuroscope*.²⁶⁻²⁸

TECHNIQUES

Thoracoscopy is an invasive technique that should be used to obtain a diagnosis when other, simpler methods are non-diagnostic (in case of pleural exudates) or to achieve pleurodesis (in case of recurrent pleural effusion or pneumothorax).^{25,29} As with all technical procedures, there is a learning curve before full competence is achieved.^{30,31} Appropriate training is therefore mandatory.^{12,31,32,33} The technique of insertion by means of a trocar is actually very similar to that of chest tube insertion. Once the pleuroscope is in the pleural space, the thoracoscopist can visualize and obtain a biopsy specimen from all areas of the pleural cavity, including the chest wall, diaphragm, mediastinum, and lung under direct visual control. When indicated, talc pouddage can be performed. In general, thoracoscopy is easier to learn than flexible bronchoscopy if sufficient expertise in thoracentesis and chest tube placement has already been gained.¹²

There are two different techniques of diagnostic and therapeutic thoracoscopy, as performed by the pulmonary physician (Video 24-1³⁴).^{12,25,35,36} In the first method, as first described by Jacobaeus for diagnostic purposes, a single entry site is usually produced with a 7- or 9-mm trocar for

a thoracoscope with a working channel for accessory instruments and optical biopsy forceps; for this technique, local anesthesia is usually employed.⁵ This approach can be modified for use of a semirigid thoracoscope (also called *pleuroscope*).²⁶⁻²⁸ In the other technique, as used by Jacobaeus for lysis of adhesions, two entry sites are used: one with a 7-mm trocar for the examination telescope and the other with a 5-mm trocar for accessory instruments, including the biopsy forceps. For this technique, conscious sedation or general anesthesia is preferred.³⁵

EQUIPMENT

Rigid instruments are still in use, as they were from the beginning.²⁵ Compared with the rigid thoroscopes, flexible bronchoscopes or other flexible endoscopes have several disadvantages, mainly less adequate orientation within the pleural cavity and small channels that limit the size of biopsy forceps, which may result in inadequate biopsy specimens. A recently modified semirigid pleuroscope with a flexible tip has become an attractive alternative.^{26-28,28a} As mentioned, the single-entry-site technique is usually performed via a 7- or 9-mm diameter trocar and a cannula with valve. Trocars are also available with diameters of 5 and 3.75 mm for performing thoracoscopy in children. Optical devices exist with various fields of view (0, 30, and 90 degrees) (Fig. 24-1). Recently mini-thoracoscopy has been introduced, with the use of a rigid optical telescope of 3 mm and a trocar with a diameter of 4 mm.³⁶ The indication for minithoracoscopy is for the evaluation of a small pleural effusion or the presence of a narrow intercostal space. A second port of entry is necessary to obtain biopsy specimens. In infants, smaller rigid equipment (3.5 mm), also used for minithoracoscopy, or instruments similar to those used in rigid bronchoscopy are employed. Biopsy forceps with the feature of viewing straight ahead to the biopsy site as well as accessory instruments such as puncture needle, cautery electrode, probe, combined suction, cautery cannula with valves, and various biopsy forceps and scissors are available. For talc pleurodesis, a talc atomizer is used.³⁵

Figure 24-1 Instruments for thoracoscopy. A, Trocar and cannula with valve. B, Single-incision thoracoscope (9 mm diameter). C, Biopsy forceps with straight optics. D, Magnified view of optical device and forceps in the thoroscope shaft ready for biopsy. (Redrawn from Loddenkemper R: Thoracoscopy—state of the art. *Eur Respir J* 11:213–221, 1998.)

Figure 24-2 The semirigid (semiflexible) pleuroscope (Olympus Corporation). Control section allows handling as with the flexible bronchoscope. (Copyright Olympus SE & Co. KG.)

The two-entry-site technique uses a 7-mm trocar for the first site of entry for appropriate telescopes and forceps and similar accessory instruments. For the second site of entry, a 5-mm trocar is used for insertion of instruments designed for its smaller bore, including a loop for dividing adhesions and a double-lumen insufflator.³⁵

As stated earlier, the semirigid (semiflexible) pleuroscope, was developed recently.²⁶⁻²⁸ The design, including the handle, is similar to that of a standard flexible bronchoscope; however, the proximal 22 cm is stiff and the distal 5 cm is bendable with an angulation of 160 and 130 degrees (Fig. 24-2). The outer diameter of the shaft is 7 mm, and a working channel of a diameter of 2.8 mm allows the use of standard instruments available for flexible bronchoscopy. The semirigid pleuroscope has several advantages. The skills involved in operating the instrument are already familiar to the practicing bronchoscopist. Because the shaft is rigid, it can be moved like the rigid thoracoscope without losing the orientation, and it is compatible with the video processors and light sources of the same manufacturer. Finally, the flexible tip permits easier visualization of the entire pleural cavity and permits a homogeneous distribution of talc on all surfaces.²⁵ Compared with rigid thoracoscopic instruments, the disadvantages of the flexible pleuroscope are the costs, the vulnerability of the scope, and the smaller biopsy specimens, although its diagnostic yield in pleural disease has been shown to be comparable with that of the conventional rigid thoracoscope.^{25,28} In addition, the flexible forceps used with the pleuroscope may not have the mechanical strength to obtain pleural biopsy specimens of sufficient depth, which may reduce the diagnostic yield in mesothelioma. This technical problem can be overcome by the use of a diathermic knife, which is also useful for the cutting of pleuropulmonary adhesions.²⁷

The procedure suite should be equipped with monopolar and, if possible, bipolar electrocoagulation as well as equipment for resuscitation and assisted ventilation, electrocardiography, and blood pressure monitoring, and a defibrillator, an oxygen source, and vacuum generators.^{5,35}

Thoracoscopy can be performed in the operating room or in an environment dedicated to invasive procedures (see Video 24-1³⁴).^{11,12,27} The personnel required to perform

thoracoscopy include an endoscopy nurse (or an endoscopy assistant) to assist with the instrumentation, an additional assistant outside the sterile field to bring necessary equipment, and the physician performing the thoracoscopy.³¹ Ideally an additional person sits at the patient's head and monitors his or her overall condition. In an emergency, thoracoscopy can be performed with only a physician and a nurse, but this is less efficient and prolongs the procedure.⁵ Medical thoracoscopy can also be performed safely in an entirely outpatient setting.^{36a}

INDICATIONS

Thoracoscopy today is primarily a diagnostic procedure, but it can also be applied for therapeutic purposes (Table 24-1).^{11,12,15,25} Thoracoscopy is mainly used for diagnosis of exudates of unknown cause, for staging of diffuse malignant mesothelioma or lung cancer, and for treatment by talc pleurodesis of malignant or other recurrent effusions.^{37,38} Thoracoscopy is also useful for evaluation and possible treatment of spontaneous pneumothorax and empyema.¹¹ For those familiar with the technique, thoracoscopy is also indicated for diagnostic biopsies from the diaphragm, lung, mediastinum, and pericardium and for more elaborate procedures.¹³⁻¹⁵ As mentioned earlier, there is an overlap of indications between thoracoscopy and VATS (see later discussion and Table 24-1). In addition, thoracoscopy offers a remarkable tool for research as a gold standard in the study of pleural effusions.

The diagnosis of pleural effusions is the main and oldest indication for thoracoscopy, as described by Jacobaeus himself in his earliest articles.^{1,4} However, even in the therapeutic era, publications from many countries emphasized the diagnostic value of thoracoscopy in spontaneous pneumothorax, focal pulmonary disease, diseases of the chest wall, mediastinal tumors, diseases of the heart and great vessels, and thoracic trauma.⁴ Later, these indications were expanded to include performing biopsies for localized and diffuse lung diseases.^{11,12} Today, the use of thoracoscopy for diagnosis of lung diseases has decreased owing to the improvements in less invasive pulmonary biopsy techniques such as flexible bronchoscopic biopsy and computed tomography (CT)-guided biopsy.^{4,12}

In the past, therapeutic thoracoscopy was used extensively for collapse treatment of tuberculosis to sever adhesions that prevented a complete artificial pneumothorax.³ This indication disappeared after the successful introduction of chemotherapy for tuberculosis.⁴ Today, the main indication for therapeutic thoracoscopy is talc poudrage in malignant or other chronic and recurrent pleural effusions.³⁸ The first report on *talcage* was published in 1935,³⁸ and in 1963 it was first used for treating recurrent effusions.⁴ Since then, talc poudrage performed during thoracoscopy for pleurodesis in malignant pleural effusions has been widely applied, especially in Europe.⁴ Talc pleurodesis via thoracoscopy has several advantages over pleurodesis via a thoracostomy tube: simultaneous drainage of pleural fluid, visualization of the visceral pleura to ensure that the lung is not encased by pleural thickening or tumor that could prevent reexpansion (Video 24-2), and guidance of chest tube placement.³⁹ In addition, talc pleurodesis can also be used to prevent recurrent pneumothorax.⁴⁰

Table 24-1 Indications for Thoracoscopy (Medical Thoracoscopy) versus VATS (Surgical Thoracoscopy)

VATS, video-assisted thoracic surgery.

Other indications for therapeutic thoracoscopy are the drainage of empyema¹⁵ or dorsal sympathectomy in hyperhidrosis patients.^{13,14} Anecdotal reports describe its use for removal of foreign bodies, for removal of benign tumors, and for production of pericardial fenestrations.¹²

CONTRAINDICATIONS

Contraindications to thoracoscopy are few and rarely absolute.²⁵ The main limitation is the size of the free pleural space, which must be at least 6 to 10 cm in width.¹² If extensive adhesions prevent the lung from collapsing away from the chest wall, thoracoscopy can still be performed (extended thoracoscopy), but this requires special skill and should not be undertaken without appropriate training.⁴¹

Several factors may make it necessary to postpone thoracoscopy but are rarely prohibitive; these include a persistent cough, hypoxemia, hypocoagulability (prolonged international normalized ratio or platelet count <40,000 to 60,000/ μ L), and cardiac abnormalities. Hypercarbia indicative of respiratory failure may prove to be an absolute contraindication, except in patients with a tension pneumothorax or massive pleural effusion, in whom it can be anticipated that thoracoscopy would provide therapeutic benefit in addition to a possible diagnosis. Under these conditions, premedication should be administered judiciously to minimize respiratory center depression. Even in very ill patients on a ventilator, diagnostic thoracoscopy has been carried out without significant complications.^{5,35}

Contraindications for pulmonary biopsy are suspicion of arteriovenous pulmonary aneurysm, vascular tumors, hydatid cysts, and a stiff fibrotic lung.^{30,42} Relative contraindications for pulmonary biopsy would include previous systemic steroid or immunosuppressive therapy because, under these circumstances, bronchopleural fistulas resulting from lung biopsy may heal poorly.

The thoracoscopist must consider the risk-benefit ratio in each case. Thoracoscopy should be performed only after careful evaluation aimed at answering specific questions.

COMPLICATIONS

Thoracoscopy is a safe and effective modality in the diagnosis and treatment of several pleuropulmonary diseases if certain standard criteria are fulfilled.^{5,25,35,43} In the most thorough review, there was only 1 death among 8000 cases, for a mortality rate of 0.01%.⁴² In another series reviewing 4300 cases, the mortality rate was 0.09%.³⁵ The reported mortality rate of thoracoscopy is thus roughly equivalent to or less than that of transbronchial biopsies. In another report of 817 thoracoscopy procedures using conscious sedation and local anesthesia, the complications were persistent air leak of more than 7 days' duration in 2%, subcutaneous emphysema in 2%, and postoperative fever in 16%.⁴⁴ The major complication rate in a series of 102 patients was 1.9% and included ventricular tachycardia responding to resuscitation, subcutaneous emphysema, and persistent air leak.⁴⁵ The minor complication rate was 7.5%, including transient air leak, fever, and minor bleeding at a biopsy site. Another large series including 360 patients reported morbidities of fever in 9.8%, empyema in 2.5%, pulmonary infection in 0.8%, and malignant invasion of the scar in 0.3%.⁴⁶ Major uncontrollable bleeding requiring thoracotomy was not reported in any of these large series and appears to be extremely rare. Many complications such as benign arrhythmias, low-grade hypotension, and hypoxemia can be prevented by administration of oxygen.⁴⁷ In case of persistent bleeding, electrocoagulation may become necessary.³⁵

Reexpansion pulmonary edema from the removal of large pleural effusions is infrequent, perhaps because immediate equilibration of the pleural pressure is provided by direct entrance of air through the cannula into the pleural

space. Bronchopleural fistulas may follow lung biopsies; if the lungs are stiff, a fistula may require longer to heal than the usual 3- to 5-day period of chest tube drainage with applied pleural suction.³⁵ Local site infection is uncommon, and empyema has been reported only very rarely.⁴² In cases of mesothelioma the late complication of tumor growth at the site of entry has been observed after thoracoscopy and also after thoracentesis or closed-needle biopsy. Radiation therapy 10 to 12 days after thoracoscopy has been reported to prevent this late complication,⁴⁸ although the standard use of prophylactic radiation therapy in these cases is controversial.⁴⁹ After talc poudrage, any postprocedure fever, as a nonspecific inflammatory reaction, and pain can be treated symptomatically. In conclusion, the overall mortality rate with thoracoscopy is extremely low. Morbidity, which is mainly due to benign postprocedural fever, is also minimal. Thoracoscopy in the hands of the appropriately trained pulmonologist is safe.⁴³

PATIENT PREPARATION

Before thoracoscopy, radiologic evaluation should routinely include a posteroanterior and a lateral chest radiograph.²⁵ Ultrasonography for localization of the pleural fluid and for diagnosis of potential fibrinous membranes or adhesions in the pleural space is helpful (see Chapter 20). In a British observational study, thoracic ultrasonography localized a safe site for thoracoscopy when not clinically apparent in 11 out of 80 cases (14%) and detected unexpected septations in 7 (9%).⁵⁰ According to the guidelines of the British Thoracic Society on pleural procedures and ultrasonography, thoracic ultrasonography is strongly recommended for all pleural procedures to localize the site of pleural fluid.⁵¹ A CT scan is not mandatory but can be helpful to localize abnormalities such as loculated empyema or localized lesions (tumors) of the chest wall or diaphragm.

Evaluation of the patient's respiratory status requires, at a minimum, arterial or capillary blood gas analysis. An electrocardiogram should be obtained to exclude recent myocardial infarction or significant arrhythmia. The clinical laboratory will provide the coagulation parameters, serum electrolyte levels, and blood glucose level as well as blood group typing, platelet count, results of liver function studies, and serum creatinine level.

The planned technique, the management of possible postoperative complications, and the expected diagnostic or therapeutic results should be explained to the patient. It is only then that the patient can truly provide informed consent.⁵

The site of introduction of the thoracoscope depends in part on the location of abnormalities to access and the location of potentially hazardous areas to avoid. Thoracoscopy is usually performed with the patient in the lateral decubitus position with the intended procedural site facing upward.^{5,11,35,52} A pillow is placed under the patient's flank, causing the spine to flex laterally and widening the intercostal spaces at the procedural site.

ACCESS TO THE PLEURAL SPACE

Because it is impossible to perform the procedure if the pleural cavity is completely obliterated, a sufficiently large

pleural space is an essential prerequisite, allowing the introduction of the trocar and thoracoscope without injuring the lung or other organs (see [Video 24-1](#)³⁴).²⁵

The simplest access is available in the setting of a preexisting complete pneumothorax or large pleural effusion, in which the trocar can be introduced directly into the pleural space without risk for injuring the lung. In the setting of a small or moderate-size pleural effusion, a needle puncture should be performed at the level of greatest opacification/dullness or, ideally, under ultrasonographic or fluoroscopic guidance. When pleural fluid is aspirated, the syringe is removed from the needle, and air enters the pleural space either spontaneously or after the patient takes a few deep breaths. The entry of air causes the lung to collapse away from the chest wall and creates a pleural space for safe trocar insertion. Alternatively, if one is certain that the needle is well positioned in the pleural fluid (e.g., not in the lung), air can be injected into the pleural space by means of a syringe. Most often, a few milliliters of air is sufficient to create a good separation of the lung from the chest wall. Greater safety is provided under ultrasonographic guidance, which allows the operator to localize the pleural effusion and to exclude thick septations/adhesions, which may prevent a sufficient collapse of the lung and thus may cause possible complications such as bleeding and injury to the lung, diaphragm, and other thoracic structures when introducing the trocar at the site of the septations/adhesions.⁵³ Another option is fluoroscopy "on the table," which can show the air-fluid level caused after injection of air, as well as the presence of any adhesions.

If neither effusion nor pneumothorax is present, an artificial pneumothorax must be created either by the blunt dissection technique using the finger⁴¹ or by the technique of pneumothorax induction. The blunt dissection technique (extended thoracoscopy) involves gentle dissection of the pleural adhesions with a finger to advance the thoracoscope into the pleural space.^{41,52} Some operators introduce carbon dioxide, instead of air, to maximize absorption rates in the unlikely event of air embolism. If so, the pneumothorax should be induced immediately before undertaking thoracoscopy, because the pneumothorax will be absorbed rapidly.^{5,12} Some thoracoscopists induce the pneumothorax the day before the procedure, allowing more time to obtain pressure measurements and to determine if the pleural space is patent, as indicated by a fluctuation of pressure with breathing between -15 and -5 cm H₂O (1 cm H₂O \cong 1 mbar).

However, some experienced teams regularly perform thoracoscopy without any form of image-guided induction of a pneumothorax. In one series of more than 700 thoracoscopies conducted without preprocedural imaging of the entry site, induction of a pneumothorax was impossible in only 10 patients, due to extensive adhesions.⁵⁴ In this series, no major complications such as bleeding were observed.

ANESTHESIA

Thoracoscopy by the single-entry-site technique is usually done under local anesthesia with premedication, together with an antianxiolytic, a narcotic, or both (e.g., midazolam and hydrocodone).²⁵ If necessary, additional pain medication should be given during the procedure, as required.

With this conscious sedation, an anesthetist is not needed. Exceptions are rare idiosyncratic or allergic sensitivities to typical anesthetics, very anxious or uncooperative patients, including children, and severe hypercarbia. An excellent alternative today is sedation by propofol with or without premedication⁵⁵; however, the use of propofol for moderate sedation is not approved in some countries, including the United States, without the supervision of an anesthesiologist.⁵⁶ General anesthesia with intratracheal intubation and ventilation is used in some centers,⁵⁷ as it is for VATS, but is not generally necessary for thoracoscopy.^{12,52}

Monitoring devices such as a cardiac monitor, oxygen saturation monitor, and automatic blood pressure monitor are applied. Some advocate the simultaneous measurement of cutaneous or exhaled carbon dioxide tension, because sedation may lead to significant hypoventilation.⁵⁸ An intravenous line is maintained, both for intravenous sedation and for possible resuscitation medications.

THORACOSCOPIC TECHNIQUE

The site of introduction of the thoracoscope should be chosen to access the location of presumed abnormalities and to avoid potentially hazardous areas such as the midanterior line, where one finds the internal mammary artery, the axillary region with the lateral thoracic artery, and the infraclavicular region with the subclavian artery (see **Video 24-1**³⁴). The region of the diaphragm is unsuitable, not only because adhesions are frequent but also because the liver or spleen may be injured.^{5,12,25,52} For general applications the trocar is introduced in the lateral thoracic region between the midaxillary and the anterior axillary line in the 4th to 7th intercostal space ("safety triangle"); for pleural effusions, in the 6th or 7th intercostal space; and for pneumothorax, in the 4th intercostal space. Following preparation with a surgical disinfectant and local anesthesia using 1% or 2% lidocaine, a small skin incision is made, and the trocar is advanced with a fairly forceful corkscrew motion until the detectable resistance of the internal thoracic fascia has been overcome. The cannula of the trocar should lie at least 0.5 cm within the pleural space. Pleural effusions should be removed by using a suction tube that does not occlude the cannula, so that air may rapidly enter the pleural space to equalize pressures. After complete removal of the effusion, or in cases without effusion, the optical device is introduced through the cannula, and the pleural space is then inspected (see **Video 24-1**³⁴) (**Fig. 24-3**).

The pleural space can be inspected directly through the thoracoscope or indirectly by viewing the image on a screen via videothoracoscopy, the standard procedure today. The advantages of videothoracoscopy over direct thoracoscopy are multiple: The view is better when projected on a screen, the other participants of the procedure (fellow, nurse, anesthesiologist) can watch the thoracoscopy, which is also important for teaching purposes, and indirect viewing provides greater sterility.

Anatomic relationships and intrathoracic structures are usually well recognized (**Video 24-3**). Biopsies of the pleura and, if needed, of the lungs, can be performed easily and safely by means of the lung biopsy forceps (**Video 24-4**). In the presence of undiagnosed pleural effusions, biopsy specimens should be taken from macroscopic lesions at the

Figure 24-3 CT representation of pleuroscopy in the right thoracic cavity with the patient in the left lateral decubitus position. Visualization of the chest wall, pleura, diaphragm, lung, and anterior (and part of posterior) mediastinum is possible. (From Loddenkemper R: Thoracoscopy—state of the art. *Eur Respir J* 11:213–221, 1998.)

anterior chest wall, the diaphragm, and the posterior chest wall for histologic evaluation and, if there is suspicion of tuberculosis, for mycobacterial culture. If no macroscopic abnormalities are visible, several biopsy specimens should be taken from different sites of the parietal pleura. Biopsy specimens from the lung are not taken routinely because of the risk for creating a fistula but may be necessary when the abnormalities are seen only on the lung surface. The likelihood of creating a bronchopleural fistula can be reduced by the use of an electrocautery biopsy forceps.⁵⁹ In cases of inflammatory pleural exudates or when several therapeutic thoracenteses have already been performed, fibrinous membranes or adhesions may be present that hinder examination. If so, these can be severed by using a blunt forceps or by cutting with electrocautery.

Although a single site of entry is generally sufficient, a second site may be useful for biopsies or to coagulate.³⁵ A second port of entry is mandatory to introduce a biopsy forceps in case of mini-thoracoscopy, in which the scope is too small to accommodate a forceps.³⁶ The position of the second site of entry can be determined by viewing through the 50-degree scope while depressing the possible entry site with the index finger. It is sometimes helpful to insert a

needle through the same site while viewing its precise location through the thoracoscope. After administration of a local anesthetic, a 5-mm incision is made and the 5-mm trocar is inserted directly. Its cannula will accommodate many instruments designed for its smaller bore.

TALC PLEURODESIS

Talc poudrage is the most widely reported method of talc instillation into the pleural space.³⁸ It is mainly used for pleurodesis in malignant or recurrent pleural effusions^{27,38,42} but is also used in persistent or recurrent spontaneous pneumothorax.⁴⁰ Thoracoscopic talc pleurodesis can be performed under local anesthesia but generally requires additional pain medication.²⁵

Before the procedure it is important to confirm that the lung can completely expand because contact of the lung with the chest wall will be necessary for a successful pleurodesis.^{38,39} Failure to expand fully may indicate a trapped lung caused by thickening of the visceral pleura (which can be confirmed at thoracoscopy) or a main-stem bronchial occlusion by tumor. If the chest radiographs fail to show a contralateral mediastinal shift in the presence of a large pleural effusion, an endobronchial obstruction should be suspected and, if possible, removed by bronchoscopy before the thoracoscopy.

During the procedure, in cases of pleural effusion it is important to remove all pleural fluid before spraying with talc. Complete collapse of the lung is desirable, because it permits wide and uniform distribution of the talc.

The optimal dose of talc for poudrage is not known, but usually a dose of approximately 5 g is recommended for malignant or recurrent effusions,³⁹ whereas for pneumothorax patients 2 g is usually sufficient.⁴⁰ The pleural cavity should be inspected during talc insufflation to ensure that the talc is uniformly distributed (Video 24-5). For this purpose one can use a thoracoscope with an angled optical device and a flexible suction catheter that is connected to a small bottle containing talc and to a pneumatic atomizer introduced through the working channel of either the thoracoscope^{35,52} (Fig. 24-4) or the semirigid pleuroscope.²⁷

After talc poudrage a 10- to 24-French chest tube should always be inserted and pointed toward the posterior costo-

vertebral gutter in patients with effusions or toward the apex in patients with pneumothorax. It is questionable if suction is necessary. If suction is applied, the use of high-volume, low-pressure systems is recommended, with a gradual increment in pressure to about -20 cm H₂O.⁶⁰ Following the procedure, chest tube removal has been recommended when the daily amount of fluid production is less than 150 mL, but there is little evidence to support this practice.⁶⁰ One report suggests that the chest tube can be removed within 24 hours without regard to daily fluid production.⁶¹ A potential advantage of talc poudrage via thoracoscopy compared with slurry delivered via chest tubes is the more even distribution of talc over the whole pleural surface.³⁹ In three head-to-head studies⁶²⁻⁶⁴ comparing talc poudrage with talc slurry instillation, talc poudrage was at least equally, and in some studies significantly more, effective, than talc slurry; slurry has never been shown to be superior to poudrage. In patients undergoing thoracoscopy, talc poudrage should therefore be the preferred method. In patients with a poor Karnofsky index, or when thoracoscopy is refused or impossible, talc slurry represents a valid alternative.

Talc is inexpensive and highly effective.⁶⁵ Its most common short-term adverse effects include fever and pain. Cardiovascular complications such as arrhythmias, cardiac arrest, chest pain, myocardial infarction, and hypertension have been noted⁶⁶; whether these complications result from the procedures or are related to talc per se has not been determined.⁶⁷ Acute respiratory distress syndrome, acute pneumonitis, and respiratory failure have also been reported after talc poudrage and slurry, especially in the United States. The development of respiratory failure is most likely due to the dose and especially to smaller particle sizes of talc,⁶⁸ which can distribute via the pleural stomata (which are the openings to the lymphatics) to the lung.⁶⁹ Ferrer and associates⁶⁹ demonstrated that the particle size of the talc used in the United States is significantly smaller than the French talc that is used in Europe (10th percentile diameter 2.4 to 3.1 μ m in the United States versus 10.5 μ m for French talc). In a review it was demonstrated that a small particle size of talc plays a key role in the development of complications after talc pleurodesis⁷⁰ via the pleural lymphatics to the rest of the body. The use of size-calibrated, larger-size talc appears to be absolutely safe in the treatment of recurrent pleural effusions and spontaneous pneumothorax.⁷¹⁻⁷⁴ Unfortunately, the large-particle size-calibrated French talc has not yet been approved for use in the United States.

RESULTS

Pleural Effusions

Even after extensive diagnostic workup of the pleural fluid, the cause of a number of pleural effusions may remain undetermined.^{12,75} Blind needle biopsies may establish the diagnosis in some additional cases, particularly in tuberculous pleurisy. In a series by Boutin and colleagues³⁰ of 1000 consecutive patients with pleural effusion, 215 cases remained undiagnosed after repeated pleural fluid analysis and performance of pleural biopsies. This is in agreement with the results of several other authors who, without the

Figure 24-4 The flexible catheter, connected to a small bottle containing talc and to a pneumatic atomizer (manual insufflator), is introduced through the working channel of the rigid thoracoscope.

use of thoracoscopy, report that at least 20% to 25% of pleural effusions remain undiagnosed, although this certainly depends strongly on the particular patient populations.¹² Because of the higher diagnostic yield and ability to induce pleurodesis in a single setting, it has been estimated in a theoretical cost analysis in the United Kingdom that medical thoracoscopy may save considerable costs in the evaluation of unexplained pleural effusions compared with other tests, including image-guided pleural biopsy.⁷⁶

Several studies have tried to determine the diagnostic accuracy of thoracoscopy in the setting of undiagnosed pleural effusion, but the results vary widely, with a range of 60% to 90%.^{30,45,77} Closer evaluation of the study designs reveals that the duration of follow-up was occasionally short and frequently not mentioned at all. One well-designed study of thoracoscopy in 102 patients reported by Menzies and Charbonneau,⁴⁵ with follow-up periods between 1 and 2 years, found a sensitivity of 91%, a specificity of 100%, accuracy of 96%, and a negative predictive value of 93%. Boutin and colleagues³⁰ reported a false-negative rate of 15% within 1 year of follow-up. In a retrospective study of 709 patients who underwent thoracoscopy for diagnosis of unexplained exudative effusions, Janssen and coworkers⁷⁷ also found a 15% false-negative rate in a long-term follow-up (minimum, 24 months) of 208 patients with initial negative results; the overall sensitivity of thoracoscopy was 91%, the specificity was 100%, the positive predictive value was 100%, and the negative predictive value was 92%.⁷⁷ Of note, even thoracotomy can miss the diagnosis. In a study of the results of thoracotomy in patients with pleural effusion of undetermined cause, even after a pathologic diagnosis of a benign pleural process, 25% of patients were diagnosed with a malignancy.⁷⁸ The diagnoses most often missed were malignant pleural mesothelioma and lymphoma (mesothelioma in 10 and lymphoma in 4 out of 31 cases,⁷⁷ and lymphoma in 6 and mesothelioma in 4 of 13 cases⁷⁸). Autofluorescence videothoracoscopy may help in the future to avoid some of the false-negative results.⁷⁹

Because of its high diagnostic accuracy, diagnostic thoracoscopy is an excellent option in cases of exudates in which the cause remains undetermined after pleural fluid analysis.^{27,39,42} The procedure allows fast and more definite biopsy diagnosis, including a high yield for tuberculosis cultures, and determination of hormone receptors in some malignancies. Furthermore, staging in lung cancer and diffuse mesothelioma is possible. The exclusion of an underlying malignancy or of tuberculosis is provided with high probability. Surgery, including surgical thoracoscopy, not only is more invasive and expensive but also does not produce better results than thoracoscopy and should therefore be reserved for very selected cases.

Malignant Pleural Effusions

Diagnosis. Malignant pleural effusions are today the leading diagnostic and therapeutic indication for thoracoscopy^{12,27,80} (Figs. 24-5 and 24-6). In a prospective comparison of different diagnostic tests, the diagnostic yield of nonsurgical biopsy methods in malignant pleural effusions was studied simultaneously in 208 patients, including 116 metastatic pleural effusions (from 28 breast cancers, 30 cancers of various other organs, and 58 cancers of unde-

Figure 24-5 View through the thoracoscope in a patient with a malignant pleural effusion due to breast cancer. One can see small whitish tumor nodules on the parietal (chest wall) pleura (*upper part of photo*). The lung surface (*lower part of photo*) demonstrates some anthracosis. (From Loddenkemper R, Mathur PN, Noppen M, Lee P: *Medical thoracoscopy/pleuroscopy: manual and atlas*, New York, 2011, Thieme.)

Figure 24-6 View through the thoracoscope in a patient with diffuse malignant mesothelioma following occupational asbestos exposure. One can see tumor nodules and whitish areas with pleural thickening on the parietal (chest wall) pleura (*upper part of photo*). Histologic examination revealed a sarcomatoid cell type. (From Loddenkemper R, Mathur PN, Noppen M, Lee P: *Medical thoracoscopy/pleuroscopy: manual and atlas*, New York, 2011, Thieme.)

termined origin); 29 cancers of the lung; 58 diffuse malignant mesotheliomas; and 5 malignant lymphomas.⁴² The diagnostic yield of pleural fluid cytologic examination was 62%, of closed pleural biopsy was 44%, and of thoracoscopy was 95%. The sensitivity of thoracoscopy was higher than that of cytologic examination and closed pleural biopsy combined (95% vs. 74%, $P < 0.001$). The combined methods were diagnostic in 97% of malignant pleural effusions (Fig. 24-7). In 6 of the 208 cases (2.9%), an underlying neoplasm was suspected at thoracoscopy but confirmed only by thoracotomy or autopsy. Similar results have been reported by a number of other investigators.^{21,29,77}

Figure 24-7 Sensitivity of different biopsy methods (cytologic and histologic results combined) for the diagnosis of malignant pleural effusions. Numbers represent sensitivity (%) of tests, either alone or combined, in a prospective inpatient comparison of 208 patients. It shows that thoracoscopy alone has 95% sensitivity for the diagnosis of malignancy; cytology and closed pleural biopsy contribute little to the total sensitivity for all three tests of 97%. (Redrawn from Loddenkemper R, Boutin C: Thoracoscopy: present diagnostic and therapeutic indications. *Eur Respir J* 6:1544–1555, 1993.)

The reasons for false-negative results of thoracoscopy include insufficient and nonrepresentative biopsy specimens, probably due to lack of experience of the thoracoscopist or the presence of fibrous adhesions preventing access to neoplastic tissue.^{35,42}

The diagnostic sensitivity of thoracoscopy is similar for all types of malignant effusion. In one study the overall yield in 287 cases was 62% for cytologic examination and 95% for thoracoscopy; the relative yields for cytologic examination and thoracoscopy did not vary greatly for lung carcinomas ($n = 67$), at 67% and 96%, respectively, for extrathoracic primaries ($n = 154$), at 62% and 95.5%, or for diffuse malignant mesotheliomas ($n = 66$), at 58% and 92%.¹²

Staging. Thoracoscopy may be useful in staging lung cancer, diffuse malignant mesothelioma, and metastatic cancer. In lung cancer patients, thoracoscopy can help to determine whether the effusion is malignant or paramalignant.⁴² As a result, it may be possible to avoid exploratory thoracotomy for tumor staging. Canto and associates⁸¹ found no thoracoscopic evidence of pleural involvement in 8 of 44 patients with lung cancer and pleural effusion; 6 proceeded to resection, where the lack of pleural involvement was confirmed. The new American College of Chest Physicians Clinical Practice Guidelines recommend that patients suspected of having lung cancer who have an accessible pleural effusion and a negative pleural fluid cytology should have a pleural biopsy, either by image-guided techniques or by thoracoscopy.^{81a}

In diffuse malignant mesothelioma (Videos 24-6 and 24-7), thoracoscopy can provide an earlier diagnosis and better histologic classification than closed pleural biopsy because of larger and more representative biopsy specimens and more accurate staging.^{82,83} Earlier diagnosis and staging may have important therapeutic implications either for surgery or for local immunotherapy or local chemotherapy, because better clinical outcomes have been observed for patients detected in the early stages (I and II).⁸²

Thoracoscopy is also helpful in the diagnosis of benign asbestos-related pleural effusion by excluding mesothelioma or malignancies. Fibrohyaline or calcified, thick, and pearly white pleural plaques may be found (see as a small part of Video 24-8), indicating possible asbestos exposure.⁸²

Thoracoscopic pulmonary biopsy specimens and even biopsy specimens from special lesions on the parietal pleura may demonstrate high concentrations of asbestos fibers and thereby provide further support for a diagnosis of asbestos-induced disease.⁸⁴

A further advantage of thoracoscopy in metastatic pleural disease is that biopsies of the visceral and diaphragmatic pleura are possible under direct observation. In addition, the larger size of thoracoscopic biopsy specimens may provide easier identification of primary tumor, including hormone receptor determination in breast cancer,⁸⁵ and improved morphologic classification in lymphomas.^{86,87} In addition, the extent of intrapleural tumor spread can be described using a scoring system that has been shown to correlate well with survival⁸⁸ and with response to talc poudrage.⁸⁹

Of recent interest is the assessment of specific mutations in lung cancer cells that can direct targeted therapy. In pleural biopsy specimens, Guo et al⁹⁰ found a rate of 70% of epidermal growth factor receptor mutations and concluded that pleural biopsy specimens, in this case obtained by VATS, provided better material than other techniques, even including surgical resection. Adequate tissue appears to be important for these assays; the reliability of cytologic examination for demonstration of epidermal growth factor receptor mutations is subject to further research.⁹¹ Direct comparative studies on epidermal growth factor receptor mutation rate of histologic and cytologic specimens are not available.

Therapy. In malignant pleural effusions, talc pleurodesis achieves success rates of more than 90% as reported in several series.³⁹ Although there is a lack of randomized controlled studies, talc poudrage seems to be the most efficient method of pleurodesis.³⁹ Diacon and colleagues,⁹² in a prospective randomized trial, compared thoracoscopic talc poudrage under local anesthesia to bleomycin instillation. In 36 patients they found much lower recurrence rates of effusion after talc poudrage (13% and 65%, respectively, after 180 days). A cost estimation also favored talc poudrage, both for initial hospitalization and with regard to recurrences. Boutin and associates³⁵ randomly compared talc poudrage and tetracycline instillation in 40 patients: after 1 month, the success rate was 90% for talc and 80% for tetracycline; however, after 9 months, talc pleurodesis persisted, whereas half had recurred after tetracycline. Fentiman and coworkers⁹³ found talc superior to tetracycline for control of pleural effusions secondary to breast cancer. Viallat and associates,⁴⁶ in a retrospective study of over 300 patients, found that talc poudrage achieved a 90% success rate at 1 month and, in 82%, produced a lifelong symphysis. The success rate in metastatic adenocarcinoma cases was higher than in mesothelioma cases. Weissberg and BenZeev⁹⁴ reported similar results in another large series with 360 cases. Aelony,⁹⁵ in a case series, observed prolonged survival averaging 22.4 months after treatment with talc poudrage pleurodesis. In vitro studies suggest that talc produces apoptosis in human malignant mesothelioma cells and might therefore have an antitumor,⁹⁶ as well as an antiangiogenic, effect.⁹⁷

In chylothorax due to lymphoma, Mares and Mathur⁹⁸ showed excellent results of talc poudrage, all in cases

refractory to chemotherapy or radiation therapy. All 19 patients with 24 hemithoraces involved had no recurrence after 30, 60, and 90 days (8 patients died during the 90 days of follow-up).

The recent development of indwelling (also called “tunneled”) pleural catheters has challenged the position of talc pleurodesis as the first option of treatment for malignant pleural effusion.⁹⁹⁻¹⁰¹ The primary goal of an indwelling pleural catheter is symptom relief by repeated drainage of pleural fluid in the home setting. The indwelling pleural catheter can induce a spontaneous pleurodesis, at a rate reported to range from 26% to 70%,¹⁰¹⁻¹⁰⁴ with a mean rate of 46%.¹⁰⁵ The spontaneous pleurodesis has been observed between 29 to 59 days.¹⁰²⁻¹⁰⁴ For daily drainage, dedicated disposable vacuum bottles are provided by the manufacturer of the drainage system. These bottles are expensive, and reimbursement by health insurance companies is not provided in many countries. Reported complications are malfunctioning of the catheter (9.1%), pneumothorax requiring chest tube (5.9%), pain (5.6%), and blocked catheter (3.7%). Less common complications are catheter fracture, empyema, cellulitis, and tumor metastasis along the catheter tract.¹⁰⁵

No randomized studies are yet available that compare thoracoscopic talc *poudrage* and indwelling pleural catheter placement. In a randomized controlled trial, talc *slurry* pleurodesis and an indwelling pleural catheter were compared with a primary end point of patient-reported relief of dyspnea; in this study no significant difference between the two methods was found in dyspnea or in quality of life. Twelve patients (22%) in the talc slurry group required further pleural procedures, which was significant compared to 3 patients (6%) in the indwelling pleural catheter group. On the other hand, significantly more patients (40%) experienced adverse events in the indwelling pleural catheter group versus 13% in the talc group.¹⁰⁶ In a cost-analysis study, talc slurry pleurodesis was found to be more cost-effective than the indwelling pleural catheter if the patient survived for more than 6 weeks.¹⁰⁷

In another study, thoracoscopic talc *poudrage* and indwelling pleural catheter placement were combined in 30 patients.¹⁰⁸ Successful pleurodesis was obtained in 92%; the indwelling pleural catheter could be removed at a median of 7.54 days. The authors stated that both length of hospital stay and duration of indwelling pleural catheter use could be reduced significantly compared to either procedure alone.

An indwelling pleural catheter placement is most likely the best treatment option in patients with a trapped lung. For all other patients the advantage of placement of an indwelling pleural catheter as opposed to thoracoscopic talc pleurodesis (or the combination of both) remains to be established. A major advantage of thoracoscopic talc pleurodesis is the possibility of obtaining a histologic diagnosis of the pleura in the same session. In future studies comparing indwelling pleural catheter and thoracoscopic talc pleurodesis, this important fact should be included in the design of the study.

❏ **Tuberculous Pleural Effusions (Video 24-8).** Although the diagnostic yield of pleural fluid culture combined with closed-needle biopsy for the diagnosis of tuberculosis is

quite high, there may be indications for thoracoscopy in otherwise uncertain pleural effusions^{12,37} (Fig. 24-8). The diagnostic accuracy of thoracoscopy is almost 100% because the pathologist is provided with multiple selected biopsy specimens, and there is a higher likelihood of obtaining the tubercle bacilli on culture.^{12,42} In this prospective inpatient comparison, an immediate diagnosis of *M. tuberculosis* infection in 100 cases was established histologically in 94% with thoracoscopy, but in only 38% with needle biopsy.^{12,42} This may be of clinical importance, because a proper histopathologic diagnosis allows antituberculous chemotherapy to be started without delay. The combined yield of histologic diagnosis and bacteriologic culture was 99% for thoracoscopy and 51% for needle biopsy, increasing to 61% when culture results from effusions were added (Fig. 24-9). The percentage of positive *M. tuberculosis* cultures from thoracoscopic biopsies (78%) was twice as high as that from pleural fluid and needle biopsies combined (39%), allowing bacteriologic confirmation of

Figure 24-8 View through the thoracoscope in a patient with a tuberculous pleural effusion. Note the numerous small whitish nodules on the parietal (chest wall) pleura (upper part of photo). The histologic examination revealed florid exudative tuberculous pleurisy with epithelioid cell granulomas, numerous multinucleated giant cells of the Langerhans type, and necrosis. *Mycobacterium tuberculosis* cultures from the biopsy specimens were positive, whereas those from the effusion were negative. (From Loddenkemper R, Mathur PN, Noppen M, Lee P: *Medical thoracoscopy/pleuroscopy: manual and atlas*, New York, 2011, Thieme.)

Figure 24-9 Sensitivity of different biopsy methods (histologic and bacteriologic results combined) for the diagnosis of *Mycobacterium tuberculosis* infection. Numbers represent sensitivity (%) of tests, either alone or combined, in a prospective inpatient comparison of 100 patients. Thoracoscopy alone has 99% sensitivity for the diagnosis of tuberculosis. (Redrawn from Loddenkemper R, Boutin C: Thoracoscopy: present diagnostic and therapeutic indications. *Eur Respir J* 6:1544–1555, 1993.)

the diagnosis and, importantly, drug susceptibility testing. In 5 of the 78 positive cases (6.4%), resistance to one or multiple antituberculous drugs was found and influenced therapy and prognosis.

Closed-needle biopsy can have high yield in areas with a high prevalence of tuberculosis, but even then thoracoscopy can have other benefits.¹⁰⁹ In a prospective study of 40 cases from South Africa, thoracoscopy had a diagnostic yield of 98% in comparison with an 80% diagnostic yield from pleural biopsies performed with an Abrams needle.¹¹⁰ In addition, thoracoscopy can lead to complete drainage of the effusion; initial complete drainage of the effusion, performed during and after thoracoscopy, was associated with greater symptomatic improvement than any subsequent therapy.¹¹¹ The positive role of early removal of the pleural fluid has also been shown recently in a double-blind, randomized, placebo-controlled trial from Taiwan.¹¹² No studies are known that compare the potential benefits of thoracoscopy, allowing early diagnosis, complete drainage, and early drug treatment, with those of drug treatment alone.

It is debatable whether to treat patients with antituberculous drugs merely on the suspicion of tuberculous pleurisy if they present with a high lymphocyte count in the pleural fluid and a positive skin test. At least in countries with a low prevalence of tuberculosis, where other laboratory tests such as adenosine deaminase may not be specific, thoracoscopy may be indicated instead of blind needle biopsies, to prove or exclude tuberculosis.¹¹³ In addition, the high yield for *M. tuberculosis* cultures from thoracoscopic biopsy specimens increases the possibility of obtaining susceptibility tests, which, in cases of drug resistance, may influence therapy and prognosis.^{12,109}

Other Pleural Effusions. For diagnosis, in cases with effusions that are neither malignant nor tuberculous, thoracoscopy may give visual clues to the cause, such as by revealing the thick white fibrin deposits seen in rheumatoid effusions, calcifications in effusions following pancreatitis, dilated veins in liver cirrhosis, or signs of trauma.^{5,42} Although for these entities the history, pleural fluid analysis, and physical and other examinations are usually helpful, thoracoscopy may be indicated to confirm the clinical suspicion.⁷⁵ If pleural effusion is secondary to underlying lung diseases such as pulmonary infarct or pneumonia, the diagnosis can frequently be made on visual examination and be confirmed by biopsy of the lung.^{5,35,42} As already mentioned, thoracoscopy is well suited for determining that a patient with a history of asbestos exposure likely has benign asbestos-related pleural effusion, which, by definition, is a diagnosis of exclusion of other causes, in particular malignancies.⁸²

For diagnosis, in the setting of other undiagnosed pleural effusions, the main diagnostic value of thoracoscopy lies in its ability to exclude malignant and tuberculous disease.^{12,75} By means of thoracoscopy, the proportion of so-called idiopathic pleural effusions usually falls below 10%, whereas in studies that have not used thoracoscopy, failure to obtain a diagnosis can exceed 20% of cases.⁷¹ However, this certainly also depends on the selection of patients and on the definition of “idiopathic.” Even after surgical exploration—the gold standard—there are still undiagnosed effusions.^{78,114}

For treatment, talc pleurodesis can be considered in some cases of nonmalignant pleural effusions that are recurrent and symptomatic and do not respond to medical therapy (Video 24-9). Such effusions may include those due to hepatic and renal hydrothorax, chylothorax, yellow nail syndrome, and systemic lupus erythematosus.¹¹⁵⁻¹¹⁷ In such patients with recurrent benign undiagnosed effusions, Vargas and colleagues¹¹⁸ achieved successful pleurodesis in 20 of 22 by talc insufflation using a thoracoscopic technique with a mediastinoscope performed under general anesthesia.

Empyema

Thoracoscopy can also be used in the management of early empyema, mainly to achieve early and complete drainage^{15,35,119,120} (Video 24-10). As a procedure intermediate between tube thoracostomy and VATS, thoracoscopy is effective and, when compared with surgical drainage, costs significantly less and avoids general anesthesia. It is particularly advisable for frail patients at high surgical risk.^{15,121} In cases with multiple loculations, it is possible to open these spaces to remove the fibrinopurulent membranes by forceps and to create a single cavity that can then be successfully drained and irrigated.¹²² If performed for this indication, thoracoscopy should be carried out early in the course of empyema, before the adhesions become too fibrous and adherent to perform thoracoscopy. Adhesions can be evaluated before the procedure by ultrasonography; thick dense adhesions may preclude thoracoscopy or talc pleurodesis.¹²³ In fact, ultrasonographic imaging before thoracoscopy significantly reduces the number of pleural access failures: it helps locate the optimal site for thoracoscopy and, in case of complete adhesion of the pleura, indicates the need for another procedure such as VATS or a CT-guided biopsy.¹²³

Thus, if the indication for placement of a chest tube is present and if the facilities are available, thoracoscopy can be performed at the time of chest tube insertion. Overall, thoracoscopy is a procedure similar to chest tube placement but one that enables the creation of a single pleural cavity, allowing much better local treatment.^{119,122,123} In a retrospective study of 41 patients, thoracoscopy was successful without further intervention in 35 (85%).¹²⁴ It was mainly successful in patients with free-flowing fluid (100%) and multiloculated empyema (92%), but in only 4 of 8 patients with an empyema in the organizational stage. However, prospective studies on the role of thoracoscopy in the treatment of early empyema in adults have not yet been published.

Spontaneous Pneumothorax

In spontaneous pneumothorax, thoracoscopy has both diagnostic and therapeutic purposes^{5,35,40,42,125-127,127a} (Fig. 24-10). Whenever a chest tube is introduced by the trocar technique, it is easy to use an optical device for visual inspection of the lung and pleural cavity before insertion of the chest tube. Special techniques, including fluorescence thoracoscopy, have been used to identify blebs and other porosities (Video 24-11).¹²⁸ By inspection during thoracoscopy, the underlying lesions can be directly assessed according to the classification of Schramel and coworkers¹²⁶: stage I, with an endoscopically normal lung; stage II, with

Figure 24-10 View through the thoracoscope in a patient with a spontaneous pneumothorax. On the surface of the lung (lower part of photo), large apical blebs are visible.

pleuropulmonary adhesions; stage III, with small bullae and blebs (<2 cm in diameter); and stage IV, with numerous large bullae (>2 cm in diameter). In 1047 cases of pneumothorax in which thoracoscopy was used by three different teams, pathologic lesions were detected in approximately 70%, with similar percentages for stages II, III, and IV.¹² In this study, blebs and bullae were detected in 45% to 62% of cases. Although the detection rates of blebs and bullae are reported to be higher (76% to 100%) in series using VATS or thoracotomy,¹²⁶ it is unlikely that large bullae and blebs or fistulas would be overlooked during thoracoscopy.

Treatment by thoracoscopy may include electrocautery of blebs and bullae (if the site of the air leak is visible) and pleurodesis using talc poudrage (Video 24-12).^{40,125} The first use of thoracoscopy for treatment of pneumothorax was in Vienna in 1937 by Sattler, who cauterized adhesions that prevented the closure of bronchopleural fistulas.⁴ Talc poudrage achieves excellent results, with recurrence rates reported below 10%.⁴⁰ A prospective study showed that, for complicated pneumothorax, defined as recurring or persistent pneumothorax, simple talc poudrage under local anesthesia prevented a recurrence of pneumothorax.¹²⁹ In a prospective, randomized, multicenter comparison, talc poudrage for primary spontaneous pneumothorax proved more efficient (only 1 of 61 patients with talc poudrage had a recurrence, compared with 10 of 47 with simple pleural drainage) and more cost-effective than drainage alone.¹³⁰ The recurrence rate after thoracoscopic talc poudrage is 5%, which is similar to the recurrence rate after VATS.¹³¹ An important disadvantage of VATS is long-term postoperative pain, which may develop in more than 30% of patients and may last for 3 to 18 months.¹³² Currently there is no

study directly comparing efficacy and complication rates of VATS and thoracoscopy.¹³¹

Other types of pneumothorax treated successfully by thoracoscopy have included those due to *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*) pneumonia, metastatic osteosarcoma, pleural endometriosis, lymphangioleiomyomatosis, and cystic fibrosis.⁷⁵

In talc poudrage for pneumothorax, a mere 2 to 4 mL of talc can be sufficient for effective pleurodesis.⁴⁰ The short-term safety of insufflation of large particle size talc in patients with spontaneous pneumothorax has recently been proven in a prospective multicenter study.⁷² In a study of patients 22 to 35 years after talc poudrage, there were no long-term sequelae; total lung capacity averaged 89% of the predicted value in 46 patients, whereas it was 97% of the predicted value in 29 patients treated with tube thoracostomy alone.¹³³ In this long-term follow-up, none of the poudrage group developed mesothelioma. Although talc poudrage may result in minimally reduced total lung capacity, as well as pleural thickening on chest radiography, these changes appear to be clinically unimportant.^{72,134} Talc poudrage may be relatively contraindicated for patients who may become candidates for lung transplantation, although currently it is not considered an absolute contraindication to lung transplantation.¹³⁵

In the United States, where large particle size talc is not yet available, apical bullectomy followed by mechanical abrasion or resection of the pleura is sometimes considered to be the procedure of choice for treatment of recurrent spontaneous pneumothorax, if apical blebs or bullae are present. It is important to add pleurodesis (chemical or mechanical) to a VATS procedure because the recurrence rate after bullectomy alone is unacceptably high, 27.5% after 10 years' follow-up in one study.¹³⁶ Mechanical pleurodesis can include abrasion or a partial parietal pleurectomy. There are a few studies comparing these approaches. When talc pleurodesis was added to the VATS procedure, Bridevaux and colleagues⁷³ found a significantly lower recurrence rate of 1.8% compared to 9.2% after partial parietal pleurectomy. In a review by Sepehrpour and associates,¹³⁷ recurrence rate after VATS pleurectomy was demonstrated to be lower than after pleural abrasion; however, there was slightly better results with talc pleurodesis than with either of the mechanical techniques.

Therefore, if the facilities are available, thoracoscopy may be performed in all patients with spontaneous pneumothorax in whom tube drainage is indicated. Several advantages are offered: precise assessment of underlying lesions under direct visual control, choice of best (conservative or surgical) treatment measures, direct treatment by electrocautery of small blebs and bullae, and severing of adhesions, if necessary, followed by talc poudrage, as well as selection of the best location for subsequent chest tube placement.⁴²

Diffuse Pulmonary Diseases

Diffuse lung diseases provide a good indication for diagnostic thoracoscopy.^{5,35,42,135,138,139} (Fig. 24-11). An overview of the entire lung surface, assisted by the magnification of the thoracoscope, allows harvesting of representative samples of abnormal areas of parenchyma. In a review of

Figure 24-11 A view through the thoracoscope in a patient with multiple pulmonary metastases due to ovarian cancer (lower part of photo).

the literature, the sensitivity of thoracoscopic lung biopsy specimens was 93% in 1031 cases with varying causes.³⁵ In a large series of 419 patients with diffuse lung diseases, the overall sensitivity was 85% with different yields depending upon the underlying disease: 98% in sarcoidosis stage II and III, 88% in malignant diseases, 85% in diffuse pulmonary fibrosis/interstitial pneumonia, and 42% in histiocytosis X.⁴² Thoracoscopy has also been used with a high diagnostic yield in immunocompromised patients.¹³⁸

In comparison with bronchoscopy, thoracoscopy is more invasive (see “[Contraindications](#)” section) but presents several advantages. It provides significantly larger samples and allows the physician to choose the biopsy site. Unlike transbronchial biopsy, thoracoscopy enables electrocautery, so that bleeding following a thoracoscopic parenchymal biopsy can be managed without difficulty. In cases where a prolonged bronchopleural fistula after biopsy can be anticipated, as in end-stage pulmonary fibrosis, thoracoscopic biopsies should be avoided in favor of a VATS biopsy with suturing or stapling. Vansteenkiste and coworkers¹³⁹ found that the required pleural drainage time (on average 5.3 ± 4.7 days) was related to the total lung capacity, which mirrors the severity and stiffness of interstitial lung disease.

With regard to sensitivity and invasiveness, thoracoscopy ranks between transbronchial biopsy and open-lung biopsy.⁴² In a recent experimental animal study, subpleural and deep lung biopsy specimens were taken during thoracoscopy in six sheep.¹⁴⁰ No significant differences were found between subpleural and deep biopsies regarding the mean quality scores of the tissue obtained. According to this study, subpleural biopsy specimens obtained during thoracoscopy might be sufficient for establishing an accurate diagnosis in diffuse parenchymal lung disease, where the subpleural layers are involved.

Localized Diseases

Localized abnormalities of the chest wall, diaphragm, and thoracic spine may be diagnosed using thoracoscopy if the

pleural space is not obliterated.^{5,42} Hyaline pleural plaques, localized pleural mesothelioma, lipoma, neurinoma, rib metastasis, rib erosions, and the like can be examined and, if necessary, biopsied. Very discrete metastases are sometimes found in the region of the diaphragm and the posterior chest wall, with or without associated pleural effusion. Chest wall lesions may be easier to diagnose than lung lesions: in a retrospective study in which 109 cases with chest wall lesions of different causes were analyzed, the diagnostic sensitivity was 83%,⁴² whereas, in solitary lung lesions, the overall diagnostic sensitivity was only 46%.

Currently the application of thoracoscopy has decreased substantially for localized disease because of better imaging techniques such as CT, magnetic resonance imaging, and ultrasonography, which allow image-guided biopsies. For example, such biopsies have proved useful for diagnosis of pleural plaques, lipomas, and cysts.¹² Alternatively, surgical thoracoscopy (VATS) will now be used for these indications, because the technique not only is diagnostic but also allows the removal of benign or malignant lesions.

DIFFERENCES BETWEEN THORACOSCOPY AND VIDEO-ASSISTED THORACIC SURGERY

As described in the preceding sections, thoracoscopy is used mainly for diagnosis of pleural diseases. The most common indications for thoracoscopy are diagnosis of pleural effusion with inspection of the pleural cavity, combined with biopsy specimens from the parietal and visceral pleura, as well as treatment of malignant or other therapy-refractory effusions by talc pleurodesis (poudrage). It is a relatively simple and inexpensive technique because it can be performed in an endoscopy room, under local anesthesia or conscious sedation, through a single entry site with nondisposable instruments.

VATS, conversely, which takes its roots from thoracoscopy, has now been technically developed to the point that it can replace thoracotomy for most indications, if certain limitations such as dense pleural symphysis are not present. VATS requires an operating room, general anesthesia with single-lung ventilation, more than two (usually three) entry sites, and complex instruments. Overall, it is a more invasive and expensive technique with a higher risk than thoracoscopy; however, in experienced hands and in the proper setting, VATS is less invasive, is less expensive, and has a lower risk than open procedures.

The different clear-cut indications for either thoracoscopy or VATS are listed in [Table 24-1](#). However, there remains a gray area of indications for which either method can be used (see [Table 24-1](#)). Gray areas include treatment of pneumothorax stages I to III, drainage of empyema stages I and II, biopsies in diffuse parenchymal lung diseases, and sympathetic nerve interventions. For these indications the choice of the medical or the surgical approach depends on local expertise, availability of the technique, and performance status and prognosis of the patient. More details are given in the book *Medical Thoracoscopy/Pleuroscopy: Manual and Atlas*.²⁵

Key Points

- Thoracoscopy (medical thoracoscopy/pleuroscopy) is less invasive than video-assisted thoracic surgery (surgical thoracoscopy) because it is performed under local anesthesia and conscious sedation, most commonly through a single entry. It is also less expensive because it can be performed in an endoscopy suite, using nondisposable rigid or semirigid endoscopes, and usually does not require an anesthesiologist.
- Thoracoscopy is used today mainly for diagnostic purposes, in particular in pleural effusions of otherwise indeterminate origin, owing to its high sensitivity and specificity for the diagnosis of malignancy and tuberculosis.
- Thoracoscopy is useful in staging diffuse malignant mesothelioma and lung cancer with pleural effusion.
- Thoracoscopy allows talc poudrage, which is a highly successful conservative method for pleurodesis in malignant and recurrent pleural effusions.
- Thoracoscopy can be useful for treatment of spontaneous pneumothorax; the introduction of the scope by the trocar technique is similar to the introduction of a chest tube, and an optical device can be used to inspect the pleural space followed by coagulation of blebs and bullae and talc poudrage.
- Thoracoscopy can be used in the management of early empyema, for biopsy diagnosis of diffuse pulmonary diseases, and for sympathectomy in hyperhidrosis patients. As an invasive procedure, it should be used only if other, simpler methods fail or are not available.
- Thoracoscopy is a safe procedure that is even easier to learn than flexible bronchoscopy if sufficient expertise in thoracentesis and chest tube placement has already been gained. As part of interventional pulmonology, it should be included in the training program of pulmonologists.

INTRODUCTION

Pulmonary function tests permit accurate, reproducible assessment of the functional state of the respiratory system. It is worth emphasizing that pulmonary function tests do not diagnose specific diseases. Different diseases cause different patterns of abnormalities in a battery of pulmonary function tests. These patterns allow us to quantify the severity of respiratory disease, which enables us to detect disease early and characterize the natural history and response to treatment. It is important to remember, however, that these conclusions are based on inferences, not specific proofs. The accuracy of our inferences depends on a complete knowledge of the physiologic basis of the functions tested, properly validated equipment, and appropriate protocols. The purpose of this chapter is to describe these pulmonary function tests, reviewing briefly their physiologic basis, their

equipment and protocol requirements, and their clinical results.

This chapter has an extended online version. A wealth of details of procedures, normal and predicted values, equations, and descriptions of techniques can be found in the online chapter.

MECHANICAL PROPERTIES OF THE RESPIRATORY SYSTEM

MEASUREMENTS OF VENTILATORY FUNCTION

The physiologic determinants of airflow during quiet breathing, maximal airflow, lung volumes, and elastic recoil are reviewed in detail in Chapter 5. [Figure 25-1](#) reviews the mechanisms involved in determining maximal airflow.

Flow

Forced Spirometry

Spirometry requires recording the volume of air inhaled and exhaled, plotted against time, during a series of ventilatory maneuvers. The resulting curves permit the

ARTERIAL BLOOD GASES

Measurements of Arterial Blood Gases

INDICATIONS. There are several reasons for performing spirometry:

1. In any occupation that is potentially hazardous to the lungs, individual workers should be monitored periodically by spirometry to detect and quantify evidence of pulmonary problems.
2. Spirometry appears to be the best method to identify smokers at risk for developing severe chronic airflow obstruction.¹
3. Spirometry can indicate the statistical risk of specific surgical procedures for a group of patients but is probably not useful for the individual patient. Arterial oxygen desaturation is a much better indicator of the probability of a high risk associated with a surgical procedure (e.g., the need for prolonged postoperative mechanical ventilation) than is spirometry.²
4. Many government agencies (e.g., the Social Security Administration) require results of spirometry to quantify impairment in patients who claim disability caused by chronic bronchitis or emphysema, as well as pneumoconioses, pulmonary fibrosis, and other pulmonary disorders.
5. Spirometric results, including peak flow rates, are extremely useful in assessing the effectiveness of treatment in asthmatic patients. These simple tests are equally valuable for quantifying the effects of treatment in patients with other forms of chronic airflow obstruction, as well as many forms of restrictive disorders.
6. Spirometry can be very sensitive for evaluating progression of disease, especially if baseline values, or results obtained early in the course of the illness, are available for comparison. Variation in the range of normal is so large that changes in serial test results are much more sensitive than a single value for detecting abnormal function. For example, changes in forced vital capacity were found to be predictive of survival time in idiopathic pulmonary fibrosis.³
7. Spirometry is an excellent screening test for detection of chronic airflow obstruction, localizing and grading a critical orifice in the central airways, but may also be useful in detecting restrictive disorders.

Figure 25-1 Model of expiratory flow limitation. *Top*, The static relationships of pleural pressure (Ppl), alveolar pressure (Palv), and intraluminal airway pressure (PAW), and airway dimensions at a fixed lung volume. *Middle and bottom*, Conditions at the onset of maximal flow and with increased expiratory effort, respectively. *Dotted lines* show static airway dimensions for comparison with the dynamic state. All three panels show pressures (cm H₂O) at the same lung volume: 60% of total lung capacity where lung elastic recoil pressure is +16 cm H₂O and equals the transpulmonary pressure (PL) (PL = Palv – Ppl). *Top*, When conditions are static, Palv is zero (i.e., atmospheric) and flow (\dot{V}) at the mouth is zero. *Middle*, The subject makes a forced expiratory effort at the same lung volume. Now \dot{V} is 6.5 L/sec driven by Palv of +36 cm H₂O. Because of the resistances down the airways from alveolus to mouth, the PAW decreases to the point where PAW = Ppl (+20 cm H₂O, which is called the *equal pressure point* [EPP] because Ppl = PAW). Between the alveolus and the EPP, the airways are not compressed, but distal to the EPP there is compression and airway narrowing, because Ppl exceeds the pressure within the airways. For this lung volume, 6.5 L/sec is the maximal flow possible (see discussion of *bottom panel*, next). *Bottom*, The subject makes a forced expiratory effort starting at the same volume as in the top and middle panels (PL = Palv – Ppl = +16). In this instance, the expiratory effort is markedly increased, reflected by the increased Ppl (+50 cm H₂O) and Palv (+66 cm H₂O). However, the flow generated is still only 6.5 L/sec because the increased effort succeeds only in compressing the airways more, dissipating the increased driving pressure across the increased resistance offered by the more narrowed airways; thus flow is maximum for this particular lung volume. (Modified from Rodarte JR: Respiratory mechanics. In *Basics of RD*, New York, 1976, American Thoracic Society.)

determination as to whether the subject has a normal ventilatory reserve or an abnormal pattern characteristic of obstructive, restrictive, or mixed ventilatory abnormalities. None of these patterns is specific, although most diseases cause a predictable type of ventilatory defect. Spirometry alone cannot establish a diagnosis of a specific disease, but it is sufficiently reproducible to be useful in following the course of many different diseases. In addition, the results of spirometry make it possible to estimate the degree of exercise limitation due to a ventilatory defect (e.g., *maximal*

Figure 25-2 Lung volume and capacity. *Volumes*: There are four volumes, which do not overlap: (1) tidal volume (VT) is the volume of gas inhaled or exhaled during each respiratory cycle; (2) inspiratory reserve volume (IRV) is the maximal volume of gas inspired from end-inspiration; (3) *expiratory reserve volume* (ERV) is the maximal volume of gas exhaled from end-expiration; and (4) residual volume (RV) is the volume of gas remaining in the lungs following a maximal exhalation. *Capacities*: There are four capacities, each of which contains two or more primary volumes: (1) total lung capacity (TLC) is the amount of gas contained in the lung at maximal inspiration; (2) vital capacity (VC) is the maximal volume of gas that can be expelled from the lungs by a forceful effort following maximal inspiration, without regard for the time involved; (3) inspiratory capacity (IC) is the maximal volume of gas that can be inspired from the resting expiratory level; and (4) functional residual capacity (FRC) is the volume of gas in the lungs at resting end-expiration.

Figure 25-3 Spirogram obtained in a normal subject showing maneuvers to determine vital capacity and forced vital capacity. On the tracing shown on the *left*, the subject breathes quietly (slow recording speed), then takes a maximal inspiration followed by a maximal expiration without concern for time (vital capacity). On the tracing shown to the *right*, after a maximal inspiration (not shown), with a rapid recording speed, the subject then exhales completely, forcefully, and as rapidly as possible (forced vital capacity).

voluntary ventilation [MVV] can be predicted from the *forced expiratory volume in 1 second* [FEV₁]⁴ and to identify the type of patient likely to develop ventilatory failure after pneumonectomy.^{5,6}

The volumes of air inhaled and exhaled with relaxed and maximal effort can be measured easily with standard equipment. Lung volumes and capacities are defined in Figure 25-2. The results are obtained and displayed in a standardized manner as a spirogram (Fig. 25-3). Tests can be performed with a simple recording spirometer, which is inexpensive enough to be standard equipment in a physician's office or the diagnostic laboratory of a small clinic or

Table 25-1 Terms Used for Spirometric Measurements

Term	Previously Used Terms	Description
Vital capacity (VC)		Largest volume measured on complete exhalation after full inspiration
Forced VC (FVC)	Timed VC, fast VC	VC performed with forced expiration
Forced expiratory volume with subscript indicating interval in seconds (FEV_t) (e.g., FEV_1)	Timed VC	Volume of gas exhaled in a given time during performance of FVC
Percentage expired in t seconds ($FEV_t\%$) (e.g., $FEV_1\%$)	Timed VC	FEV_t expressed as percentage of FVC
Forced midexpiratory flow ($FEF_{25\%-75\%}$)	Average flow rate during middle 50% of the FVC	Maximal midexpiratory flow
Forced expiratory flow with subscript indicating volume segment (FEF_{V1-V2}) (e.g., $FEF_{200-1200}$)	Maximal expiratory flow rate	Average rate of flow for a specified segment of FVC, most commonly 200–1200 mL in adults
Maximal voluntary ventilation (MVV)	Maximum breathing capacity (MBC)	Volume of air a subject can breathe with voluntary maximal effort for a given time

Modified from Kory RC: Clinical spirometry: recommendation of the Section on Pulmonary Function Testing, Committee on Pulmonary Physiology, American College of Chest Physicians. *Dis Chest* 43:214, 1963.

hospital. Recommended criteria for acceptable performance standards for equipment have been published.⁷ Although normal values have been established in a spectrum of subjects of different sex, age, size, and ethnic background, few have been reported using the standards of the *American Thoracic Society* (ATS).⁸⁻¹¹ Many samples are deficient in older subjects. Almost no data exist concerning the proper prediction equations to use in individuals of foreign extraction after the family has lived in the United States for several generations. Some regression equations that include “weight” as a determinant yield absurd values in very obese subjects.¹² All these measurements depend heavily on patient understanding and cooperation and must be conducted by a well-trained technician able to communicate instructions clearly.

MAXIMAL-EFFORT EXPIRATORY VITAL CAPACITY. To obtain a maximal-effort expiratory vital capacity (VC), the subject inhales maximally to *total lung capacity* (TLC) and then exhales as rapidly and forcefully as possible. When volume is recorded on the y-axis and time on the x-axis, the resulting curve is called the *forced vital capacity* (FVC) curve. Analysis of this curve permits computation of the volume exhaled during the time following the start of the maneuver (*forced expiratory volume over time*, or FEV_t), the ratio of FEV_t to total FVC, and average flow rates during different portions of the curve. The terms used in clinical spirometry, including these different components, are summarized in Table 25-1.¹³

Several useful variables may be derived from the maximal-effort FVC.

FORCED EXPIRATORY VOLUME OVER TIME. The FEV_1 is the measurement of dynamic volume most often used in conjunction with the FVC in analysis of spirometry (Fig. 25-4). The measurement incorporates the early, effort-dependent portion of the curve and enough of the midportion to make it reproducible and sensitive for clinical purposes. *Forced expiratory volume* (FEV) measurements taken at 0.5, 0.75, 2.0, and 3.0 seconds add little information to the FEV_1 measurement. The *forced expiratory volume exhaled in 6 seconds* (FEV_6) is useful, however, because it closely approximates FVC, has been shown to be a valid alternative to the conventional FEV_1/FVC , and is easier for patients with severe airflow obstruction to attain.¹⁴ In addition, the end of the

Figure 25-4 Measurement of forced expiratory volume in 1 second. This diagram illustrates measurement of forced expiratory volume in 1 second (FEV_1) using the back-extrapolation method to define time zero (i.e., the point during the forced vital capacity [FVC] maneuver when the subject began to blow as hard and as fast as possible). A solid horizontal line (a) indicates the level of maximal inhalation. A heavy dashed line (b) passes through the steepest portion of the volume-time tracing. The intersection point of these two lines becomes time zero, from which timing is initiated, as indicated; 1 second after time zero, the vertical dashed line is drawn, indicating FEV_1 , and 5 seconds later, another vertical dashed line is drawn, indicating FVC.

test is more clearly defined, permitting more reliable correspondence between measured and referenced values.¹⁵ Furthermore, as demonstrated by Swanney and associates,¹⁵ the degree of airflow obstruction, reflected in the FEV_1/FEV_6 obtained from spirometry, can serve as an independent predictor of subsequent decline in lung function; it may therefore be used to detect smokers at higher risk for developing *chronic obstructive pulmonary disease* (COPD).¹⁵

FORCED EXPIRATORY VOLUME OVER TIME AS A PERCENTAGE OF FORCED VITAL CAPACITY. The ratio of FEV_t to total FVC has been defined precisely in healthy subjects.¹⁶ It declines with age, but abnormally decreased ratios indicate airway obstruction; normal or increased ratios do not reliably exclude airway obstruction, particularly in the presence of

Figure 25-5 Determination of forced expiratory flow between 25% and 75% of total lung capacity ($FEF_{25-75\%}$). A heavy dashed line connects two points on the volume-time curve of the forced vital capacity (FVC) maneuver. One point is marked when 25% of the FVC has been exhaled (2 L); the other point is marked when 75% of the FVC (6 L) has been exhaled from the level of maximal inhalation indicated by the solid line (a). In this example, the elapsed time between these two points is 1 second; thus the calculated $FEF_{25-75\%}$ is 4 L/sec. FEV_1 , forced expiratory volume in 1 second.

a decreased FVC. When the FVC is decreased by an interstitial process or by chest wall restriction, and the airways are normal, the FEV_1/FVC ratio is increased. (The FEV_1/FVC ratio may also be increased in subjects who fail to make a maximal effort throughout the expiratory maneuver.) The absence of an increased ratio in patients in whom one would expect the ratio to be increased suggests the presence of concomitant airway obstruction. Absolute flow may be increased initially, probably because of outward traction of increased elastic forces on airway walls. However, because flow is volume dependent, it eventually decreases in restrictive disorders without airway obstruction, although precise quantification for the various types of pure restrictive disorders is not available. Examining exhaled volumes and flows as a percentage of predicted values may facilitate interpretation of the spirogram in patients with mixed ventilatory defects.

AVERAGE FORCED EXPIRATORY FLOW. The $FEF_{25-75\%}$, or forced expiratory flow between 25% and 75% of FVC, was introduced as the maximal midexpiratory flow rate (Fig. 25-5). This measurement was intended to reflect the most effort-independent portion of the curve and the portion most sensitive to airflow in peripheral airways, where diseases of chronic airflow obstruction are thought to originate.¹⁷ These properties have gained support from clinical experience and theoretical analysis,¹⁸ and the $FEF_{25-75\%}$ is widely used currently. However, the $FEF_{25-75\%}$ shows marked variability in studies of large samples of healthy subjects, and the 95% confidence limits for normal values are so large that they limit its sensitivity in detecting disease in an individual subject.^{6,19}

Flow-Volume Relationships

GENERAL PRINCIPLES. The widespread availability of computer-based electronic pulmonary function test appa-

Figure 25-6 The flow-volume curve. The tracing of the flow-volume curve is recorded during maximal inspiration and expiration in a normal subject.

ratus permits flow-volume curves to be as readily available in the physician's office as spirometry. All of the indications for spirometry probably apply equally to the flow-volume curve. This maneuver requires the subject to inspire and expire fully with maximal effort into an instrument that measures flow and volume simultaneously. These values are plotted on the two axes of an x-y recorder or computer monitor (Fig. 25-6). As summarized in Figure 25-1, analysis of these curves has contributed to the basic understanding of the mechanical events that limit maximal exhalation. Maximal flow clearly depends on lung volume: for every point on the lower two thirds of VC, a maximal flow exists that cannot be exceeded regardless of the effort exerted by the subject. Thus maximal flow must depend on mechanical characteristics of the lungs. Flow-volume curves also provide a useful way to display ventilatory data for diagnostic purposes.

By superimposition of repeated curves using graphic means or a computer, a maximal flow-volume envelope can be constructed for any subject. This envelope represents the maximal flow values of which the respiratory system is capable, and it may exceed the airflow rates achieved in any single maneuver. As illustrated in Figure 25-7, the maximal flow-volume envelope can be approximated by having the subject make repeated trials of increasing effort or by having the subject cough repeatedly while flow-volume relationships are recorded. The flow-volume curve and FEV -time curve are mathematically interchangeable; either one can be derived graphically, or by computer analysis, from the other. This relationship can provide an internal check on the accuracy of the tests. Spirometric values can be computed from flow-volume curves. Thus values for both forced expiratory tests can be obtained with fewer efforts while still defining the maximal capacity of the respiratory system accurately. From a practical point of view, this means that the subject can generate the needed data with fewer maximal efforts and in a shorter time.

On forced exhalation, the flow-volume curve has a characteristic appearance. The curve shows a rapid ascent to peak flow and subsequently a slow linear descent proportional to volume. The initial portion of the curve (the first

Peak Expiratory Flow Rate. Expiratory flow reaches a transient peak early in the forced expiratory maneuver. Peak flow manifests during the most effort-dependent portion of the expiratory maneuver, so decreased values can result from even slightly submaximal effort rather than from airway obstruction. Nevertheless, the ease of measuring peak flow with an inexpensive, small, portable device²⁰ has made it a popular means of following the pattern of airflow obstruction on an ambulatory basis. For example, the test is used to monitor patients suspected of having occupational asthma and those who seem insensitive to the severity of bronchospasm. When a maximal effort is made, peak flow is largely a function of the caliber of large airways; it is also influenced by the transient flow caused by expulsion of air from compressed central airways. For these reasons, peak flow is abnormally decreased only in moderate to severe airway obstruction.

The national program to improve the management of patients with asthma based on the National Heart, Lung, and Blood Institute expert panel report^{21,22} depends heavily on spirometry as well as the informed use of peak flowmeters for proper patient care. These devices are sufficiently accurate that peak flow measurements made in the morning and evening (before and after bronchodilator treatments) enable patients to participate effectively in their own care. The test provides a quantitative estimate of airway lability (change in peak flow > 20%) that correlates well with more sophisticated measures of airway hyperresponsiveness obtained by provocation testing. It also provides correlation of the clinical course with pulmonary function on a daily basis, provides an early warning that pulmonary function is deteriorating, and may be used as the basis of an action plan of treatment carried out by the patient.

Maximal Voluntary Ventilation. The *maximal voluntary ventilation* (MVV) measurement is defined as the maximal volume of air that can be moved by voluntary effort in 1 minute. Subjects are instructed to breathe rapidly and deeply for 15 to 30 seconds, ventilatory volumes are recorded, and the maximal volume achieved over 15

consecutive seconds is expressed in liters per minute. Lung volumes are reported at the largest size possible within the chest and at body temperature (37°C) and standard pressure fully saturated with water vapor (760 mm Hg).

The observer should demonstrate the test; then the subject should choose his or her own respiratory rate and perform several practice runs. The respiratory frequency used in the MVV should be noted and recorded as a subscript (e.g., MVV₉₀ or MVV₁₁₀). Maximal levels are usually achieved between 70 and 120 breaths/min, but the choice of frequency does not greatly affect the test.²³

This test is heavily dependent on subject cooperation and effort. Loss of coordination of respiratory muscles, musculoskeletal disease of the chest wall, neurologic disease, and deconditioning from any chronic illness, as well as ventilatory defects, decrease MVV, so the test is nonspecific. The MVV is decreased in patients with airway obstruction, but less so with mild or moderate restrictive defects because rapid, shallow breathing can compensate effectively for the decreased lung volume.

Despite these caveats, MVV can be useful in special circumstances. It correlates well with subjective dyspnea and is useful in evaluating exercise tolerance. It appears to have prognostic value in preoperative evaluation, possibly because the extrapulmonary factors to which it is sensitive are also important for recovery from a surgical procedure.²⁴ It also provides a measure of respiratory muscle endurance that may be important in the evaluation of respiratory muscle fatigue, whether from obstructive or restrictive ventilatory defects or from specific neuromuscular diseases.²⁵ In myasthenia gravis, for example, the patient can often produce maximal efforts for a short time, so that FVC and maximal inspiratory and expiratory pressures are normal. However, the effort cannot be sustained, so the MVV or repeated FVC values decrease, even within 12 to 15 seconds. The respiratory crisis of myasthenia gravis may happen rapidly and lead to respiratory failure. As a result, some investigators have suggested that MVV should never be measured in patients with myasthenia gravis, except under carefully controlled circumstances when it may be useful in evaluating treatment.⁶

Figure 25-7 Flow-volume curves created by increasing effort and by coughing. Top, Expiratory flow-volume curve recorded during a series of expirations with increasing efforts, finally producing a maximal flow-volume envelope. Bottom, Expiratory flow-volume curve recorded during coughing (solid line), approximating the maximal flow-volume envelope (dashed line).

25% to 33% of the VC exhaled) depends on effort. As a subject exerts increasing effort during exhalation, associated with increasing intrathoracic pressure, increasing flow is generated. This portion of the curve has limited diagnostic use because its appearance depends primarily on the subject's muscular effort and cooperation rather than on the mechanical characteristics of the lung.

Shortly after development of peak flow, the curve follows a remarkably reproducible, effort-independent envelope as flow diminishes in proportion to volume until *residual volume* (RV) is reached. For each point on the volume axis, a maximal flow exists that cannot be exceeded regardless of the pressure generated by the respiratory muscles. Although this portion of the curve is very reproducible in a given subject from time to time, it is altered in a characteristic manner by the effect of diseases on the mechanical properties of the lungs. In most subjects older than age 30 and in patients with pulmonary disease, RV is determined by airway closure, so the flow-volume curve shows a progressive decrease in flow until RV is reached. In some young individuals, however, and perhaps in some patients with chest wall disease, RV is determined by chest wall rigidity, which limits maximal exhalation. In such cases, expiratory flow abruptly decreases to zero at low lung volumes.

On forced *inhalation*, the flow-volume curves are normally entirely effort dependent. The shape of the inspiratory portion is symmetrical with flow, increasing to a

maximum midway through inspiration and then decreasing as inhalation proceeds to TLC. It is less influenced by diffuse airway or parenchymal disease. When central airway obstruction is suspected, the inspiratory limb of the flow-volume curve has great diagnostic usefulness, whereas ordinary spirometry reveals a nonspecific pattern.

OBSTRUCTIVE VENTILATORY DEFECTS. Some studies suggest that early asymptomatic airway obstructive disorders may be associated with decreased maximal flow at low lung volumes,²⁶ but sufficient numbers of anatomic studies that correlate findings in patients with emphysema and with central and peripheral airway lesions are not available.^{17,27} The variability of the flow-volume curve at low lung volumes has made it difficult to interpret individual curves even when compared with studies of large populations.²⁸

In patients with obstructive ventilatory patterns, peak flow is diminished. However, it is probable that abrupt emptying of large central airways associated with vigorous exhalation causes these central airways to be compressed, generating a brief period of relatively high flow, which preserves peak flow relative to flow at lower lung volumes. Furthermore, the usual linear descent of the flow-volume curve is disrupted by an exaggerated concavity of the descending limb of the curve. This curvilinear portion of the lower half of the flow-volume curve is characteristic of obstructive ventilatory patterns and suggests the presence of airflow obstruction even when the FVC, FEV₁, and FEV₁/FVC ratio are well preserved.^{29,30,30a}

This loss of linearity relates to the severity of the obstruction as well as the type of disease. A decrease in volume is seen in conjunction with both obstructive and restrictive ventilatory defects, reflecting decreased VC. The decrease is relatively less in airway obstruction than in restrictive ventilatory defects, so the characteristic flow-volume curve in obstructive ventilatory defects tends to have its major axis oriented along the horizontal (volume) axis; in restrictive defects, the major axis appears to be along the vertical (flow) axis (see “[Pathophysiologic Patterns](#)” section).

When the tidal volume loop is superimposed on the flow-volume curve, comparison of the two may be useful in clinical evaluation. The difference between flow during tidal breathing and flow during maximal effort is a measure of pulmonary reserve. As the severity of airflow obstruction increases, the expiratory flow during the two maneuvers becomes superimposed, at first low in the lung volume, and then, as the disease becomes more severe, at higher lung volumes.

“Negative effort dependence” is present when expiratory airflow rates during quiet breathing exceed those during maximal effort. When present, this phenomenon suggests that the airways are less stable than normal, as may be seen in emphysema and in some forms of chronic bronchitis. (See later discussion of obstructive ventilatory defect in “[Pathophysiologic Patterns](#)” section for further details about this phenomenon.)

Finally, the relative position of the two curves on the volume axis is a graphic measure of the amount of expiratory volume in reserve. As this reserve decreases due to obesity, pregnancy, or ascites, the tidal volume loop moves closer to the RV.

Two other factors that affect flow-volume curves are upper airway obstruction and gas density.

Figure 25-8 Flow-volume curves obtained from patients with upper airway obstruction. Dashed line represents a curve obtained from a normal subject with the same vital capacity as that observed in the patients. Solid line indicates a curve obtained from a patient with intrathoracic obstruction (left) and from another patient with extrathoracic obstruction (right).

UPPER AIRWAY OBSTRUCTION: STENOSIS AND MALACIA. Flow-volume curves may be especially helpful in identifying tracheal or other upper airway lesions as a cause of obstruction.³¹ Central airway obstruction (i.e., proximal to the tracheal carina) that is located within the thorax produces a plateau during forced exhalation instead of the usual rise to and descent from peak flow (Fig. 25-8). When more than 50% of the VC has been exhaled, the curve then follows the usual flow-volume envelope to RV. In patients with stridor, particular attention should be paid to the configuration of the inspiratory portion as well as the expiratory portion of the flow-volume curve. Lesions located in the trachea within the thorax cause decreased airflow particularly during exhalation; during inhalation, the posterior tracheal membrane is pulled out by negative intrathoracic pressure, so increased effort increases airflow rates and the inspiratory limb of the flow-volume curve can appear normal. Conversely, tracheal lesions located outside of the thorax cause decreased airflow during inhalation; during inhalation, the tracheal membrane is sucked in and is usually associated with stridor. It is possible to estimate the diameter of a stenotic lesion by analysis of the flow-volume curve with an accuracy of ± 1 mm (eFig. 25-1), but the length of the flow-limiting segment must be confirmed by *computed tomography* (CT) scan to plan surgical correction, if required. Because a critical orifice located at the thoracic outlet is not affected by pressure above or below the lesion, airflow is limited equally during both inhalation and exhalation.³² Similarly, if a lesion is fixed and not altered by surrounding pressures, whether intra- or extrathoracic, airflow should be limited equally during inhalation and exhalation.

RESTRICTIVE VENTILATORY DEFECTS. The increase in lung elastic recoil that accounts for the decrease in VC seen with restrictive defects also increases the force driving expiratory flow and pulling outward on airway walls; thus, the usual flow-volume curve in restrictive ventilatory defects is tall and narrow. Peak expiratory flow is relatively preserved, and the descending portion of the expiratory limb is linear, decreasing rapidly from peak flow to RV. The loop often

maintains a nearly normal shape but appears miniaturized in all dimensions.

Lung Volumes

Vital Capacity and Other Static Lung Volumes. The measurement of VC requires the subject to inhale as deeply as possible and then to exhale fully, taking as much time as required. Figure 25-2 illustrates the subdivisions of lung volume.³⁷ The measurement can also be obtained by adding two of its components: the expiratory reserve volume, obtained by having the subject exhale maximally from the resting end-tidal level; and the inspiratory capacity, obtained by having the subject inspire fully from the resting end-tidal level. The sum of these two measurements yields the “combined VC”; as long as the resting end-tidal lung volume is the same for the two component maneuvers, the combined VC and the VC are equal. In patients with severe airflow obstruction the combined VC appears to be larger than the VC, suggesting the presence of poorly ventilated regions of lungs, or so-called trapped gas. This result probably reflects increased transmural pressure, which tends to cause airway closure during a large portion of the single maneuver—but only in the portion near RV during the combined VC maneuver.

A similar inference can be made by comparing the “slow VC” (performed without regard to time) and FVC, or by comparing inspired VC (maximal volume inhaled from RV to TLC) with the expired VC maneuver just described. Except for those subdivisions involving RV, each of the defined volumes can be recorded and measured by simple spirometry. The RV can be measured only by indirect methods (e.g., nitrogen washout, helium dilution, or body plethysmography). Figure 25-2 illustrates the fact that VC can be decreased in two different ways: by a decrease in TLC or by an increase in RV. Only measuring RV and TLC can differentiate these two causes.

The cause of a reduction in VC can often be inferred by analysis of maximal expiratory flow. Abnormally decreased flows support the diagnosis of an obstructive ventilatory defect, suggesting that the decreased VC is due to an increased RV (as in asthma, chronic bronchitis, and emphysema). Normal values for airflow make an obstructive ventilatory defect unlikely and suggest that a decrease in VC may be due to a decreased TLC. Restrictive ventilatory defects (e.g., pulmonary fibrosis, resection of lung tissue) decrease VC by decreasing TLC. Thus the finding of decreased VC alone is inadequate and nonspecific to assess decreased ventilatory reserve. Performance of complete spirometry (i.e., FVC and its subdivisions as well as VC) adds clarification of the mechanism and the severity of a ventilatory defect. Measurement of RV provides convincing proof of the presence or absence of overinflation or underinflation of the lungs.

Gas Dilution Methods. The two most commonly used gas dilution methods for measuring lung volume are the *open-circuit nitrogen* (N_2) method and the *closed-circuit helium* (He) method. Both methods use a physiologically inert gas that is poorly soluble in alveolar blood and lung tissues, and both are most often used to measure *functional residual capacity* (FRC), the volume of gas remaining in the lung at the end of a normal expiration. In the *open-circuit* method,

GAS DENSITY. Comparison of flow-volume curves obtained when the subject is breathing air and breathing low-density gas mixtures such as “heliox” (80% helium, 20% oxygen) has been advocated to detect early airway obstruction³³ or localize the site of obstruction.¹⁴ During a forced exhalation, when flow limitation develops in large central airways where flow is turbulent, a low-density gas such as heliox increases maximal flow (defined by the increased maximal flow at 50% VC, or $\Delta\dot{V}_{\max_{50\%}}$). As lung volume decreases, the flow-limiting segment moves into small peripheral airways, where flow is laminar and density independent. At this lung volume, air and heliox flow-volume curves can be superimposed; the lung volume at which flow becomes density independent is called the volume of isoflow. Clinical application of heliox in detecting airflow obstruction is generally not performed because a number of controversial issues have not been resolved.³⁴⁻³⁶

all exhaled gas is collected while the subject inhales pure oxygen. By assuming values for the initial concentration of nitrogen in the lungs (alveolar nitrogen fraction varies slightly with the respiratory quotient but is assumed to be approximately 0.81) and, for the rate of nitrogen elimination from blood and tissues (about 30 mL/min), measurement of the total amount of nitrogen washed out from the lungs permits the calculation of the volume of nitrogen-containing gas present at the beginning of the maneuver (Fig. 25-9). In the *closed-circuit* helium dilution method

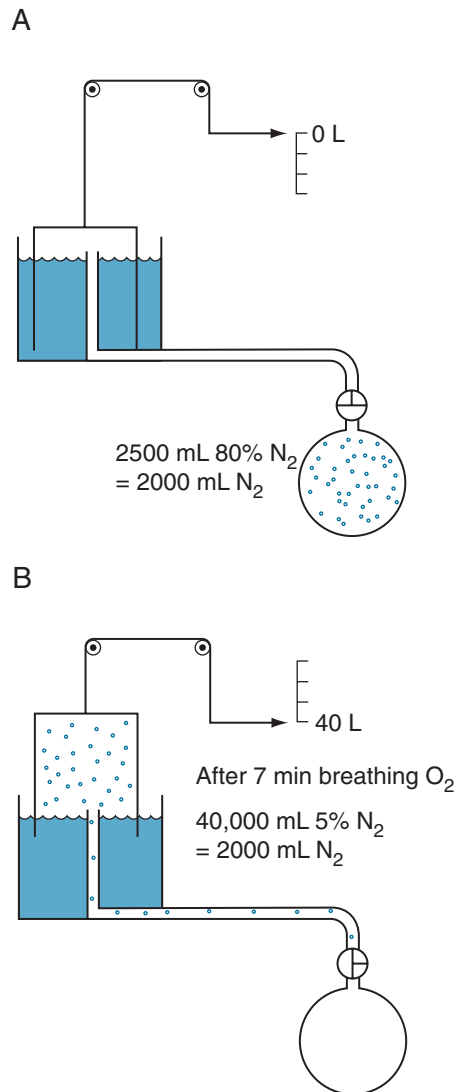

Figure 25-9 Open-circuit nitrogen method to measure functional residual capacity. Dots represent nitrogen (N_2) molecules. **A**, Initially all the N_2 molecules are in the lungs (as 80% N_2). **B**, When N_2 -free oxygen ("pure O_2 ") is breathed, the N_2 molecules are washed out of the lungs and collected with the O_2 as expired gas in the spirometer. The spirometer contains 40,000 mL of mixed expired gas with a N_2 concentration of 5%. Thus the spirometer contains $0.05 \times 40,000 = 2000$ mL of N_2 ; the remaining 38,000 mL of gas is mainly O_2 used to wash the nitrogen out of the lungs, plus some carbon dioxide. The 2000 mL of N_2 was distributed within the lungs at a concentration of 80% N_2 when the washout began; therefore the alveolar volume in which the N_2 was distributed was $2000/0.8 \text{ mL} = 2500 \text{ mL}$. Corrections must be made for the small amount of N_2 washed out of the blood and tissue when O_2 is breathed and for the small amounts of N_2 in "pure O_2 ."

(Fig. 25-10), the theory is similar. The subject rebreathes a gas mixture containing helium, a physiologically inert tracer gas, in a closed system until equilibration is achieved. If the volume and concentration of helium in the gas mixture rebreathed are known, measurement of the final equilibrium concentration of helium permits calculation of the volume of gas in the lungs at the start of the maneuver.

Body Plethysmography

TYPES OF PLETHYSMOGRAPHS. There are three types of plethysmographs: pressure, volume, and pressure-volume.

PRESSURE (CLOSED-TYPE) PLETHYSMOGRAPH. This type of plethysmograph has a closed chamber with a fixed volume

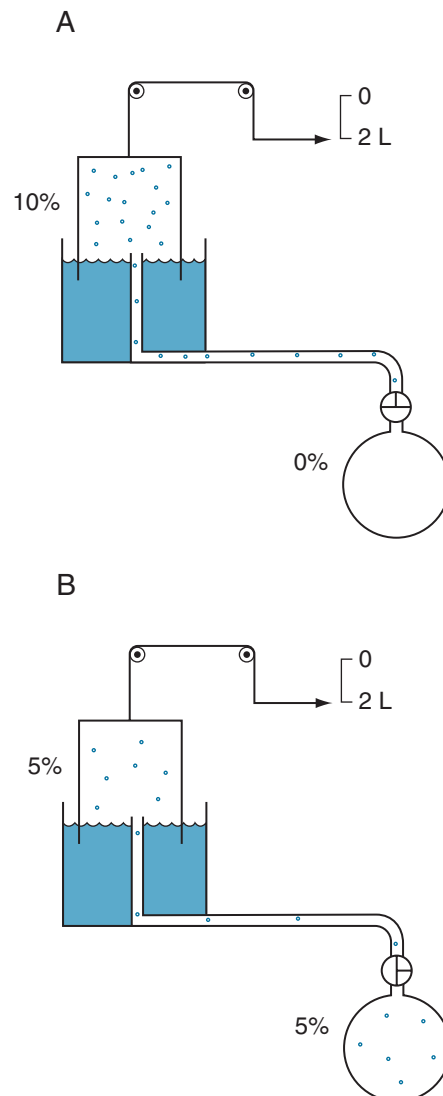

Figure 25-10 Closed-circuit helium method to measure functional residual capacity. Dots represent molecules of helium (He). **A**, Initially, all He molecules are in the spirometer (as 10% He), and no molecules are in the lungs. If the spirometer contains 2000 mL of gas, of which 10% is He, then $2000 \text{ mL} \times 0.1$, or 200 mL, of He is present in the spirometer before rebreathing. **B**, Rebreathing results in redistribution of the He molecules until equilibrium develops, at which time lung volume can be calculated. At the end of the test, the same amount of He (200 mL) must be redistributed in the lungs, tubing, and spirometer, assuming that He is inert and not soluble in blood or tissues.

An advantage of the open-circuit method is that it also permits an assessment of the uniformity of ventilation of the lungs by analyzing the slope of the change in nitrogen concentration over consecutive exhalations, by measuring the end-expiratory concentration of nitrogen after 7 minutes of washout,³⁸ or by measuring the total ventilation required to reduce end-expiratory nitrogen to less than 2%.³⁹ The open-circuit method is sensitive to leaks anywhere in the system (especially at the mouthpiece) and to errors in measurement of nitrogen concentration and exhaled volume. If a pneumotachygraph is used to measure volume, attention must be paid to the effects of viscosity changes in the exhaled gas, because it contains a progressively decreasing concentration of nitrogen. The open-circuit method shares several disadvantages with the closed-circuit method: it does not measure the volume of gas in poor communication with the airways (e.g., lung bullae); it assumes that the volume at which the measurement was made corresponds to the end-expiratory point on the spirometry tracing used to calculate expiratory reserve volume and inspiratory capacity (needed for the computation of RV and TLC from the measured FRC); and it requires a long period of reequilibration with room air before the test can be repeated. Measuring spirometric volumes immediately before measuring FRC as a combined, continuous sequence can eliminate the assumption of a constant or reproducible end-expiratory volume. This can be achieved with appropriate valves connected to the mouthpiece, which are available in many commercial systems.

Closed Circuit Methods. The closed-circuit helium dilution method (see Fig. 25-10) is similar in its basic theory. It involves having the subject rebreathe a gas mixture containing helium, a physiologically inert tracer gas, in a closed system until equilibration is achieved. If the volume and concentration of helium in the gas mixture rebreathed are known, measurement of the final equilibrium concentration of helium permits calculation of the volume of gas in the lungs at the start of the maneuver.

In a closed-circuit method, a thermal-conductivity meter measures the helium concentration continuously, permitting return of the sampled gas to the system. Because the meter is sensitive to carbon dioxide, and because carbon dioxide must in any case be removed from a closed system, a carbon dioxide absorber is added. The removal of carbon dioxide results in a constant fall in the volume of gas in the closed circuit, as oxygen is consumed and the subject produces carbon dioxide. An equivalent amount of oxygen is therefore introduced as an initial bolus or as a continuous flow. In either case, it is important that the subject be

“switched into” the system at the end-tidal point. It is possible to calculate the correction for an error in this point, but only if the subject is able to relax and exhale reproducibly to the actual end-tidal point while breathing from the circuit. In a cooperative subject the closed-circuit method also permits the measurement of inspiratory capacity, expiratory reserve volume, and VC from maneuvers recorded on the spirometer while the subject is switched into the system. This eliminates dependency on the identity of the value of end-tidal lung volume (FRC) at the time that the closed-circuit measurement is made and at the time that the subdivisions of spirometric volumes are measured.

Like the open-circuit method, the closed-circuit method is sensitive to errors caused by gas leaks and alinearity of the gas analyzer. It also fails to measure the volume of gas in lung bullae, and it cannot be repeated at short intervals. The test nevertheless gives reproducible results (the *standard deviation* [SD] of repeated measurements is 90 to 160 mL),⁴⁰ and normal values are available from several studies of healthy subjects.^{6,41}

Two other measurements of lung volume can be obtained from the dilution of gases used in standard tests of lung function. One involves measurement of the mean concentration of nitrogen in the air exhaled after the VC inspiration of pure oxygen in the single-breath nitrogen washout test of the distribution of ventilation.⁴² The other involves measuring the change in concentration of the neon, helium, or methane used as the inert tracer gas in the single-breath measurement of the *diffusing capacity for carbon monoxide* (DL_{CO}).⁴³ Indeed, the alveolar volume achieved during performance of the standard diffusing capacity maneuver is approximately TLC and must be calculated in order to measure DL_{CO} . Although the lung volume calculated from the single-breath nitrogen washout test of distribution is reported rarely, the TLC calculated from measurement of DL_{CO} is used commonly in many pulmonary function laboratories. Because the time for dilution of the tracer gas is short (10 seconds), true TLC is underestimated in patients with severe airway obstruction or uneven distribution of ventilation. FEV_1 /FVC must be less than 0.40 for TLC measured by single-breath dilution to be underestimated significantly. In healthy subjects and in patients with mild airflow obstruction, the values obtained correspond well with those obtained by body plethysmography.^{6,44}

Radiographic Methods. TLC and FRC can be estimated from chest radiographs, although what is measured is the combined air and tissue volume of the lungs; this is in contrast to the communicating gas volume that is measured by gas dilution methods and the compressible gas volume that is measured by body plethysmography.⁴⁵

in which the subject breathes the gas in the plethysmograph (or body box) (Fig. 25-11). Volume changes associated with compression or expansion of gas within the thorax are measured as pressure changes in gas surrounding the subject within the box. Volume exchange between lung and box does not directly cause pressure changes, although thermal, humidity, and carbon dioxide–oxygen exchange differences between inspired and expired gas do cause pressure changes. Thoracic gas volume and airway resistance are measured during rapid maneuvers, so small leaks are tolerated or are introduced to vent slow thermal-pressure drift. This device is best suited for measuring small volume changes because of its high sensitivity and excellent frequency response. It need not be leak-free, absolutely rigid, or refrigerated because the measurements are usually brief and are used to study rapid events.

THORACIC GAS VOLUME. The thoracic gas volume is the compressible gas in the thorax, whether or not it is in free communication with airways. By Boyle's law, pressure times the volume of the gas in the thorax is constant if its temperature remains constant ($PV = P'V'$). At end-expiration, *alveolar pressure* (P_{alv}) equals *atmospheric pressure* (P) because there is no airflow; V (thoracic gas volume) is unknown (eFig. 25-5). Then, the airway is occluded and the subject makes small inspiratory and expiratory efforts against the occluded airway. During inspiratory efforts, the thorax enlarges (ΔV) and decompresses intrathoracic gas, creating a new thoracic gas volume ($V' = V + \Delta V$) and a new pressure ($P' = P + \Delta P$). A pressure transducer between the subject's mouth and the occluded airway measures the new pressure (P'). It is assumed that the *mouth pressure* (P_{mouth})

Figure 25-11 Pressure (closed-type) plethysmograph. The subject breathes through a shutter/pneumotachygraph. The shutter is open during tidal breathing and for measurements of airway resistance, and closed for measurements of thoracic gas volume. When the shutter is closed, mouth pressure (equal to alveolar pressure at no flow) is measured by a pressure transducer (1). The pneumotachygraph measures airflow with another transducer (2), and the flow signal is integrated to volume electronically. The plethysmograph pressure is measured by a third transducer (3). The signals from the three transducers are processed by a computer. Excess box pressure caused by temperature changes when the subject sits in the closed box is vented through a valve.

equals P_{alv} during compressional changes while there is no airflow at the mouth, because pressure changes are equal throughout a static fluid system (Pascal's principle). Accordingly,

$$PV = P'V' = (P + \Delta P)(V + \Delta V) \quad (2)$$

$$0 = P\Delta V + \Delta PV + \Delta P\Delta V \quad (3)$$

$$\text{If } \Delta P \ll P, \text{ then } \Delta P\Delta V \approx 0 \quad (4)$$

$$V = -\frac{\Delta V}{\Delta P}P \quad (5)$$

where P equals atmospheric pressure minus water vapor pressure (in mm Hg), assuming that alveolar gas is saturated with water vapor at body temperature; ΔV equals change in thoracic gas volume; and ΔP_{mouth} equals change in P_{mouth} , which is equal to the change in alveolar pressure (ΔP_{alv}). Then the thoracic gas volume is calculated as follows:

$$V = -\frac{\Delta V(\text{mL})}{\Delta P_{alv}(\text{cm H}_2\text{O})} \times (P - 47 \text{ mm Hg})(1.36 \text{ cm H}_2\text{O}/\text{mm Hg}) \quad (6)$$

If a closed plethysmograph is used, ΔV is detected measuring increased plethysmographic pressure with a sensitive pressure transducer. If plethysmographic pressure is displayed on the x-axis and P_{mouth} P_{alv} is displayed on the y-axis of an oscilloscope (Fig. 25-12), the slope of the line

Figure 25-12 A closed, constant-volume, variable-pressure whole-body plethysmograph. As described in eFigure 25-5, at end-expiration airflow is zero, thoracic gas volume (V) = functional residual capacity, and alveolar pressure (P_{alv}) = mouth pressure (P_M) = barometric pressure (P_{bar}). The rectangle represents the plethysmograph. When the subject inhales against an occluded shutter in the airway, airflow remains zero, but V increases by ΔV to V' and $P_M (= P_{alv})$ increases by ΔP ($P + \Delta P$) to equal P' . When P_M is plotted against box pressure (P_{box}), the slope of the line (α) yields $\Delta V/\Delta P_{alv}$, and $V = \Delta V/\Delta P_{alv} \times P_{bar}$, as indicated in the text. \dot{V} , airflow. (Modified from Comroe JH Jr, Forster RE II, DuBois AB, et al: *The lung: clinical physiology and pulmonary function tests*, ed 2, Chicago, 1962, Year Book.)

VOLUME (OPEN-TYPE) PLETHYSMOGRAPH. This type of plethysmograph (eFig. 25-2) has constant pressure and variable volume. When thoracic volume changes, gas is displaced through a hole in the box wall and is measured either with a spirometer or by integrating the flow through a pneumotachygraph (or flowmeter). This device is suitable for measuring small or large volume changes. To attain good frequency response, the impedance to gas displacement must be very small. This requires a low-resistance pneumotachygraph, a sensitive transducer, and a fast, drift-free integrator, or meticulous use of special spirometers; consequently this form of plethysmography is challenging and is used in the research setting only.

PRESSURE-VOLUME PLETHYSMOGRAPH. This device (eFig. 25-3) combines features of both the closed and open types. As the subject breathes from the room, changes in thoracic gas volume compress or expand the air around the subject in the box and also displace it through a hole in the box wall. The compression or decompression of gas is measured as a pressure change; the displacement of gas is measured either by a spirometer connected to the box or by integrating airflow through a pneumotachygraph in the opening. At every instant, all of the change in thoracic gas volume is accounted for by adding the two components (pressure change and volume displacement). This combined approach has a wide range of sensitivities, permitting all types of measurements to be made with the same instrument (i.e., thoracic gas volume and airway resistance, spirometry, and flow-volume curves). The box has excellent frequency response and relatively modest requirements for the spirometer. The integrated flow version dispenses with water-filled spirometers and is tolerant of leaks.

In this type of plethysmograph, changes in lung volumes are computed from measurements of both *box pressure* (P_{box}) and volume displacement to determine accurately

the true volume change regardless of amplitude or frequency. P_{box} is multiplied by a *constant* (K_{box}) proportional to the gas volume in the box (i.e., by total box volume minus patient volume). P_{box} is also divided by the *box flowmeter resistance* (R_{box}) and multiplied by the integral of box flow to obtain the *box volume* (V_{box}). These two signals are added together to yield the change in lung volume (ΔV):

$$\Delta V = P_{box}K_{box} + \frac{P_{box}}{R_{box}} \int \dot{V} \quad (1)$$

The physical principles underlying this type of plethysmograph are illustrated in eFigure 25-4. The displacement volume, $\int \dot{V}$, is added to the plethysmograph compression volume, $P_{box}K_{box}$, to produce the “true” volume. If the volume change were instantaneous, the “true” volume event would be as illustrated in eFigure 25-4A. During this rapid inspiration, pressure in the plethysmograph increases abruptly and then decays exponentially (see eFig. 25-4B). If the plethysmograph flowmeter has a linear response, the plethysmograph flow signal (see eFig. 25-4C) will have a shape similar to that of the pressure signal (see eFig. 25-4B). The plethysmograph flow signal is integrated to determine volume (see eFig. 25-4D). The integrated flow signal attains the same level as that of the “true” volume event, but the shape of the integrated flow signal does not conform to that of the “true” volume event. The difference between the two waveforms is due to compression of the large volume of gas in the plethysmograph and is directly proportional to plethysmograph pressure. Thus, by adding a portion of the plethysmograph pressure to the integrated plethysmograph flow, the “true” volume event may be reconstructed accurately (see eFig. 25-4E) using Equation 1. The relative contributions of these two variables vary with frequency, but when added together, they always yield the total ΔV .

(α) can be measured during panting efforts against the closed airway:

$$V = \frac{(P - 47 \text{ mm Hg})(1.36 \text{ cm H}_2\text{O/mm Hg}) \times \text{box calibration (mL/cm)}}{\alpha \times \text{pressure calibration (cm H}_2\text{O/cm)}} \quad (7)$$

$$V = \frac{970 \times \text{box calibration}}{\alpha \times \text{pressure calibration}} \quad (8)$$

The thoracic gas volume usually measured is slightly larger than FRC unless the shutter is closed precisely after a normal tidal volume is exhaled. Connecting the mouthpiece assembly to a valve and spirometer (or pneumotachygraph and integrator), or using a pressure-volume plethysmograph, makes it possible to measure TLC and all its subdivisions in conjunction with the measurement of thoracic gas volume.

TECHNICAL PROBLEMS. As might be expected, several problems may complicate these measurements. The most important are the following.

EFFECTS OF HEAT, HUMIDITY, AND RESPIRATORY GAS EXCHANGE RATIO. Effects of heat, humidity, and respiratory gas exchange ratio cause difficulties in obtaining stable baselines.

CHANGES IN OUTSIDE PRESSURE. Outside pressure changes can make it difficult to detect the “signal” relative to “noise.”⁴⁶

COOLING. Refrigeration is required for many of these boxes, but it can cause a variety of problems related to vibration and localized cooling (e.g., a cool body and a warm head may result because of poor circulation currents).

UNDERESTIMATION OF MOUTH PRESSURE. Stanescu and colleagues⁴⁷ have reported that, in patients with asthma, lung volume measured by plethysmograph may be overestimated owing to an underestimation of P_{alv} by measurements of P_{mouth} .

COMPRESSION VOLUME. Commercial plethysmographs are now available that correct for these problems; some of these devices also take into account the compression of thoracic gas during a forced expiration.

Airway Resistance

GENERAL PRINCIPLES. Airway resistance (RAW) is easy to measure and is always related to the lung volume at which it is measured. It is useful to detect diseases such as asthma that are associated with increased airway smooth muscle tone. This can be accomplished by demonstrating that RAW is abnormally increased relative to lung volume, or by inducing significant relaxation of bronchomotor tone by administration of bronchodilator drugs. The test is very sensitive in detecting increased airway smooth muscle tone induced by provocative stimuli. This approach is useful in the assessment of nonspecific hyperirritability in response to pharmacologic agents, exercise, or cold air, or in response to specific agents such as allergens or chemicals (e.g., isocyanates) that are associated with occupational asthma (see “Bronchial Provocation” section). Measurements of RAW may also be useful in differential diagnosis of the type of airflow obstruction or localization of the major site of obstruction.

RAW is measured during airflow and represents the ratio of the driving pressure (between the alveoli [P_{alv}] and mouth [P_{mouth}]) and instantaneous airflow (\dot{V}). In a closed plethysmograph, inspiration of 500 mL of gas from the box into the lungs increases plethysmographic pressure. At the start of inspiration, thoracic gas volume enlarges, and P_{alv} (previously at atmospheric pressure) becomes subatmospheric throughout inspiration; thus alveolar gas occupies a larger volume. This decompression of thoracic gas is equivalent to adding a small volume of gas to the plethysmograph, so its pressure increases (as measured by a sensitive pressure transducer). The reverse results during exhalation, when alveolar gas is compressed. Thus \dot{V} is measured continuously with a pneumotachygraph, P_{mouth} is measured with a pressure transducer connected to a side tap in the mouthpiece, and P_{alv} is estimated continuously with the body plethysmograph (Fig. 25-13).

Figure 25-13 Measurement of airway resistance by plethysmography. The rectangle represents a closed, constant-volume, variable-pressure, whole-body plethysmograph, as in eFig. 25-5. The subject is represented by a single alveolus and its conducting airway. The top pressure transducer measures pressure within the plethysmograph, or box pressure (P_{box}). The middle pressure transducer measures the pressure drop across the pneumotachygraph connected in series with the open shutter to the airway, which yields airflow (\dot{V}). The bottom pressure transducer measures airway pressure (alveolar pressure during no flow, or P_{alv}). During inspiration, the alveolus enlarges by ΔV from the original volume (broken line) to a new volume (solid line); during expiration, the alveolus returns to its original volume. Throughout inspiration, alveolar gas (previously at atmospheric pressure) is subatmospheric and therefore occupies more volume. This is the same as adding this increment of gas volume resulting from decompression of the alveolar gas to the plethysmograph, so P_{box} increases and is recorded by the sensitive P_{box} transducer. The reverse happens during expiration when alveolar gas is compressed. Thus alveolar pressure can be monitored throughout the respiratory cycle. When \dot{V} is plotted against P_{box} , the slope of the line (β) yields the ratio of $\Delta P_{\text{box}}/\dot{V}$ as indicated in the text. (Modified from Comroe JH Jr, Forster RE II, DuBois AB, et al: *The lung: clinical physiology and pulmonary function tests*, ed 2, Chicago, 1962, Year Book.)

In practice, RAW is determined by measuring the slope (β) of a curve of plethysmograph pressure (x-axis) displayed against airflow (y-axis) on a computer monitor during rapid, shallow breathing through a pneumotachygraph within the plethysmograph. Then, a shutter is closed across the mouthpiece, and the slope (α) of plethysmographic pressure (x-axis) displayed against Pmouth (y-axis) is measured during panting under static conditions. Because Pmouth equals Palv in a static system, the second step serves two purposes. First, it relates changes in plethysmographic pressure to changes in Palv in each subject. Palv is effectively measured during flow, provided that the ratio of lung to plethysmographic gas volume is constant, because Palv for a given plethysmographic pressure is the same whether or not flow is interrupted. Second, it relates RAW to a particular thoracic gas volume:

$$RAW = \frac{\alpha}{\beta} \times \frac{PM \text{ calibration}}{\dot{V} \text{ calibration}} - R_{EXT} \quad (9)$$

$$RAW = \frac{PM}{\Delta V} \times \frac{\Delta V}{\dot{V}} - R_{EXT} \quad (10)$$

$$RAW = \frac{PM}{\dot{V}} - R_{EXT} \quad (11)$$

$$RAW = \frac{Palv}{\dot{V}} - R_{EXT} \quad (12)$$

where PM calibration is Pmouth calibration (cm H₂O per cm), \dot{V} calibration is pneumotachygraph calibration (L·sec per cm), and R_{EXT} is resistance of breathing through mouthpiece and pneumotachygraph (cm H₂O per L/sec).

Physiologic Factors. Several physiologic factors affect the values obtained during plethysmographic measurement of RAW.

AIRFLOW. RAW relates to a particular flow rate during continuous pressure-flow curves, so the slope may be read at any desired airflow rate. In general, RAW is measured at low flows, at which transmural compressive pressures across the airways are small and the relation to Palv is linear. RAW will be increased transiently with forced respiratory maneuvers in which airflow rates become limited by large transmural compressive pressures across the airways, by maximal dynamic airway compression, and by possible alterations in airway smooth muscle tone. Thus, to avoid artifacts, the standard approach is to measure RAW at low flows.

VOLUME. Near TLC, resistance is small, but, near RV, resistance is large. Lung volume may be changed voluntarily to evaluate RAW at larger or smaller volumes in health and disease.

TRANSPULMONARY PRESSURE. RAW is related directly to lung elastic recoil pressure at any lung volume. Subjects with increased lung elastic recoil have a lower RAW at a given lung volume than normal subjects because of increased tissue tension pulling outward on airway walls. In contrast, loss of elastic recoil results in loss of tissue tension and decreased traction on airway walls, so RAW is increased. This relationship may be used to analyze the mechanism of airflow limitation in various obstructive ventilatory defects (e.g., bullous lung disease).^{48,49}

AIRWAY SMOOTH MUSCLE TONE. The airways are affected markedly by smooth muscle tone, depending on the state of inflation and the subject's previous pattern of breathing (referred to as "volume history").⁵⁰ These relationships are relevant to diseases in which smooth muscle tone is increased (e.g., asthma) or low lung volumes are encountered (e.g., during cough). Thus, bronchoconstriction is not demonstrable temporarily after a deep breath or at TLC in healthy subjects. Similarly, RAW in healthy subjects may be greater when a given lung volume is reached from RV than from TLC.

PANTING. Panting minimizes changes in the plethysmograph caused by thermal, water saturation, and carbon dioxide-oxygen exchange differences during inspiration and expiration; hence these factors may be neglected if measurements are made during panting. Panting also improves the signal-to-drift ratio, because each respiratory cycle is completed in a fraction of a second; gradual thermal changes and small leaks in the box become insignificant compared with volume changes attributable to compression and decompression of alveolar gas. The glottis stays open, rather than varying its position as it does during tidal breathing. Abdominal pressure changes are also minimized.

QUIET BREATHING. Increasingly laboratories are using commercial plethysmographs that estimate RAW during so-called quiet breathing, relying on computer software rather than panting to compensate for the effects of humidity, temperature, and gas exchange. In fact, the subject must breathe at higher than normal frequencies and tidal volumes to estimate RAW using this software. The limitation to this approach is that the average resistance values tend to be slightly higher than those observed during

panting because the glottis is often partially closed during the measurement. Nonetheless, more and more laboratories are switching to this approach.

Stanescu and Rodenstein⁵¹ have demonstrated that, to avoid overestimation of thoracic gas volume, as described previously, panting must be done at 1 Hz; however, to measure RAW and avoid the temperature artifact, panting must be done at approximately 2 Hz, as advocated originally by DuBois and colleagues.⁵² This difference in the panting rates necessary for accurate measurements may prove impractical for clinical use. Alternatively, both artifacts may be avoided if the subjects breathe quietly at *body temperature* (37°C) and *standard pressure fully saturated with water vapor* (760 mm Hg) (BTPS) or may be compensated for electronically.⁵³

RAW measured plethysmographically is not the average of unequal resistances throughout the lungs; rather, it is the average Palv per unit volume divided by average airflow rate at the mouth. It corresponds to average *airway conductance* (GAW). $GAW = G_1 + G_2 + \dots + G_n$, which is equivalent to adding resistances in parallel according to reciprocals: $1/RAW = (1/R_1) + (1/R_2) + \dots + (1/R_n)$. The control of these physiologic influences is often critical in determining specific factors that influence GAW (or RAW) in a particular subject (e.g., loss of lung elastic recoil, airway smooth muscle spasm).

Lung Elastic Recoil

General Principles. Lung elastic recoil is an important physiologic characteristic of the lungs, which may change in qualitatively different ways in various diseases. In general, elastic recoil is increased in a restrictive ventilatory defect associated with decreased lung volumes. Conversely, in almost all forms of airflow obstruction, elastic recoil is decreased. Testing for elastic recoil is time-consuming, difficult to perform, expensive, and invasive. Thus the test may not be practical for the routine evaluation of patients with restrictive ventilatory defects but may be of great value in the assessment of various obstructive ventilatory defects, including those with isolated bullae or advanced emphysema, to determine whether patients will benefit from resection of nonfunctioning or very poorly functioning lung tissue. In other patients, it may be useful to differentiate emphysema from asthma or bronchitis. In evaluating patients with mixed ventilatory defects (e.g., emphysema plus fibrosis), the test may confirm the presence of both disorders.

Lung elastic recoil pressure, or *transpulmonary pressure* (PL), is the difference between the pressure inside the lungs (the alveolar pressure) and the pressure outside the lungs (the *pleural pressure* [Ppl]): $PL = Palv - Ppl$. To maintain a sustained inspiration at a volume of three fourths of TLC with the mouth and glottis open, the muscles of inspiration must maintain a pleural pressure of approximately 12 cm H₂O below atmospheric pressure ($Ppl = -12$ cm H₂O). Under conditions of no flow and pressures at the mouth, alveoli, and atmosphere are equal: $PL = 0 - (-12$ cm H₂O). If the muscles of inspiration relax, allowing the chest wall to recoil inward, Ppl rises from -12 to 0 cm H₂O and Palv from 0 to +12 cm H₂O at the instant before flow begins. This example illustrates two of the principles that underlie measurement of lung recoil: (1) the pressure required to expand

Impulse Oscillometry and Forced Oscillation Methods to Measure Respiratory Resistance (Rather Than Airway Resistance).^{54,55} DuBois and colleagues⁵² described an oscillatory method to measure the mechanical properties of the lung and thorax. In contrast to the methods already described, the oscillation techniques use an external loudspeaker or similar device to generate and impose flow oscillations on spontaneous breathing, rather than using the respiratory muscles. Impulse oscillometry measures RAW and lung compliance independently of respiratory muscle strength and patient cooperation. Sound waves at various frequencies (3 to 20 Hz) are applied to the entire respiratory system (airways, lung tissue, and chest wall); a piston pump can be used to apply such pressure waves around the body in a whole-body respirator. With modern computer methods, the slow frequency changes in pressure, flow, and volume generated by the respiratory muscles during normal breathing are subtracted from the raw data, permitting analysis of the pressure-flow-volume relationships imposed by the oscillation device (eFig. 25-6).

The elastic forces (pressures) of the lungs and chest wall oppose the volume changes induced by the applied pressure, which decrease as the frequency of oscillation increases. The total force or pressure that opposes the driving pressure applied by the loudspeaker, which can be measured as peak-to-peak pressure difference divided by peak-to-peak flow, is a combination of the resistance and reactance, which itself has elastic and inertial components. The reactance reaches a minimum at loudspeaker frequencies of approximately 3 to 8 Hz, where the resistance produces the only opposing force. This resistance is proportional to the RAW in healthy subjects and patients, although it does include a small component of lung tissue and chest wall resistance, as well as the resistance of the airways.

Values for the pulmonary resistance and total respiratory resistance primarily reflect RAW. The portion due to lung tissue resistance is about one fifth of the pulmonary resistance in healthy subjects. It is increased in patients with pulmonary fibrosis or kyphoscoliosis,⁵⁶ but rarely to a level of clinical importance where it becomes the limiting resistance. The total resistance of the respiratory system (airway + lung + chest wall, or $R_T = R_{AW} + R_L + R_{CW}$) usually is about 25% greater than the resistance of the airways in healthy subjects, or not much greater than pulmonary resistance. Again, although the chest wall resistance may be elevated in conditions such as kyphoscoliosis or parkinsonism, it rarely attains a level of clinical significance.

If the airways, lungs, and chest wall behaved as if they were a single bellows with frictional resistance, elasticity, and inertia, then the oscillations in airflow into and out of the lungs caused by the driving pressure produced by the loudspeaker across the respiratory system could be described as a function of the applied frequency by the following equations. At any frequency, the magnitude and phase shift of the reflected waves give a measure of impedance (Z) and reactance (X). The impedance is described by

$$Z = \sqrt{R^2 + \left(2\pi fL - \frac{1}{2\pi fC}\right)^2} \quad (13)$$

where Z is mechanical impedance (cm H₂O per L/sec) and is analogous to electrical impedance, R is resistance (cm H₂O per L/sec), L is electrical inductance (cm H₂O per L/sec²) and is analogous to electrical inductance, C is compliance (L/cm H₂O) and is analogous to electrical capacitance, and

f is the frequency of the driving pressure applied by the loudspeaker (Hz, or cycles per second).

The second equation describes the phase angle or lag (Θ) of the flow with respect to the applied pressure wave:

$$\tan \Theta = \frac{X}{R} = \frac{2\pi fL - \frac{1}{2\pi fC}}{R} \quad (14)$$

The inertial reactance ($2\pi fL$) corresponds to the electrical inductive reactance, which increases with frequency. The elastic reactance ($2\pi fC$) corresponds to the electrical capacitance, which decreases with increasing frequency.

The frequency at which the absolute values of these reactances are equal is called the resonant frequency. According to the Equation 14, the impedance (Z) becomes equal to the resistance of the respiratory system at the resonant frequency, which can be calculated from the following equation:

$$\text{Resonant frequency} = \frac{1}{2\pi\sqrt{LC}} \quad (15)$$

Landser and coworkers⁵⁷ developed a device based on multiple frequencies (pseudorandom noise) in contrast to Dubois and colleagues⁵² and Michaelson and coworkers,⁵⁸ who used a random noise signal. The technique requires little of the subject but to simply breathe quietly on a mouthpiece for 30 seconds; the computer does the complete analysis, yielding values for respiratory resistance at different frequencies. (The same device simultaneously estimates respiratory inductance and dynamic compliance.) This approach has been used extensively in Europe because it is fast, noninvasive, and reproducible; moreover, it seems to yield clinically meaningful results in healthy subjects before and after use of a bronchodilator, as well as in the evaluation of airflow obstruction in COPD, asthma, and congestive heart failure.⁵⁹⁻⁶¹

It should be noted that the lungs and chest wall rarely respond to a driving pressure with diverse frequencies in the same way as a simple model assumed to be composed of single values of resistance, compliance, and inductance, as described earlier. The resonant frequency of the ribs is 7 to 10 Hz, whereas the resonant frequency of the abdomen and diaphragm is about 3 Hz. The air in the trachea, bronchi, and bronchioles has an inertial reactance that is significant at relatively high frequencies (≈ 6 Hz or greater). Consequently, when the whole system appears to be at resonant frequency, the impedance is probably not a pure resistance at all, but rather an admixture of other forces of the lungs and chest wall, as described earlier.⁶²⁻⁶⁵

Bijaoui and colleagues⁶⁶ have taken advantage of the impact of cardiogenic oscillations on the adjacent lungs to estimate mechanical output impedance of the lung. They observed that the beating heart creates small oscillations in flow that can be measured at the mouth when the glottis is open. Using the Fourier-domain ratio of these oscillations in pressure and flow, Bijaoui and coworkers calculated the respiratory impedance to be between 1.5 and 10 Hz. The real portion was similar to or smaller than the resistance measured simultaneously by the forced oscillation method. They suggested that they are measuring the flow resistance of the central and upper airway. This approach may prove to be useful to obtain information about the mechanical properties of the lungs without the need for an external source of applied flow.

a lung to any volume is equal to the recoil pressure at that volume, and (2) under conditions of no flow, with the glottis open, P_{alv} and P_{mouth} are identical. It is easy to measure P_{mouth} ; absolute lung volume can be measured by any of a variety of methods already discussed; and the change in volume can be measured easily with a spirometer. All that is needed to measure lung elastic recoil pressure and lung compliance is a measurement of P_{pl} in relation to lung volume.

Because the esophagus passes through the pleural space, it seems reasonable to assume that pressure within the esophagus approximates P_{pl} . This assumption works as long as the sphincters of the upper and lower esophagus are competent and there is no force compressing the esophageal lumen, such as active contraction of the esophageal muscles or passive compression by surrounding mediastinal structures. Most of these conditions are met in subjects without esophageal disease who are sitting or standing upright.

Analysis

COMPLIANCE. When the balloon is in place, the relationship between changes in lung volume and changes in P_{pl} can be measured.

Dynamic lung compliance refers to the ratio of the change in volume to the change in pressure over a tidal breath, with the pressure measured at moments of zero flow during breathing. Measurement of dynamic lung compliance at increasing respiratory frequencies allows estimation of the frequency dependence of compliance. A fall in dynamic lung compliance as frequency increases implies narrowing of some of the airways subtending alveoli. Thus, in the absence of abnormalities in total RAW or FEV_1 (which, as described previously, are largely determined by resistance in large airways), decreased dynamic lung compliance suggests possible narrowing of small, peripheral airways.⁶⁸

Static lung compliance is the slope of the pressure-volume curve of the lung obtained during deflation from TLC.

The data obtained are conveniently expressed in terms of lung compliance, the ratio of the change in lung volume to the change in P_{pl} . However, it is clear that lung compliance changes with lung volume, with the highest values observed at volumes around FRC and lower values prevailing as the lungs are expanded more nearly to TLC (Fig. 25-14). Compliance therefore is usually reported as the slope of the curve at the point 0.5 L above FRC. However, when this convention is used, the value expressed for lung compliance is influenced by the determinants of FRC, rather than simply by the relationship between lung volume and distending pressure. Another value commonly calculated is the *coefficient of retraction* (lung elastic recoil pressure at TLC divided by TLC). Normal values are available for both compliance and the coefficient of retraction, although the great variability of these measurements limits their utility in individual patients. Because lung compliance is so dependent on lung volume (compliance can fall by 50% with resection of one lung, for example, even though the elastic properties of the remaining lung are unaltered), its variability can be somewhat reduced by correcting it for height, predicted TLC, or measured FRC.⁶⁹

Maximum information about lung elastic recoil can be derived by analyzing the whole curve, when, for example,

Figure 25-14 Static pressure-volume curve of the lungs during deflation in a normal subject. Measurements were obtained during five different maneuvers. FRC, functional residual capacity; TLC, total lung capacity.

static lung elastic recoil pressure is plotted against lung volume expressed as a percentage of *predicted* TLC.⁷⁰ Such a plot often makes it obvious whether a reduction in TLC is a function of the inability to generate an adequate lung elastic recoil pressure due to neural, muscular, or chest wall disease or is caused by a true loss of lung compliance. If lung compliance is reduced, it can still be difficult to determine whether the abnormality is due to a true increase in elastic forces or to a decrease in the number of alveoli communicating with the airways (see later discussion).

CLINICAL APPLICATIONS OF FLOW-VOLUME RELATIONSHIPS

Normal Values

Spirometric values vary with height, gender, age, and ethnicity. Publications describing reference populations should include not only the prediction equations but also a means to define their lower limits. A lower limit can be estimated from a regression model: for spirometry, values below the 5th percentile are taken as below the “lower limit of normal.”²⁸ There is no statistical basis for the common practice of using 80% of the predicted normal values for FEV_1 and FVC as the lower limit of normal in adults. In fact, Miller et al⁷¹ studied 11,413 patients and found that using fixed cut points to determine whether lung function is abnormal could misdiagnose more than 20% of patients, which they found could be avoided by using the lower limit of normal based on the 5th percentile values.

Changes in Function over Time. Changes in spirometric measurements can represent a true change or merely variability. A real change is more likely when a series of tests shows a consistent trend. A change varies in significance depending on the variable measured, the time period, and the type of patient. When the FVC and VC are followed in healthy, normal subjects, within-day changes of 5% or more, between-weeks changes of 11% to 12% or more, and

Protocol for Measurement of Lung Elastic Recoil.

To preserve the patency of a tube placed in the esophagus to measure esophageal pressure, it is necessary to cover the end of the tube with a balloon. This complicates the situation, for now intraballoon pressure is assumed to reflect intraesophageal pressure, which in turn is assumed to reflect the surrounding Ppl. The artifacts caused by the balloon generally cause the measured pressure to be too positive, owing to the compression of the balloon by the walls of the esophagus (eFig. 25-7). A long (10 cm), narrow (2.5-cm perimeter), thin-walled (0.04 cm), highly compliant latex balloon containing a small amount (0.2 to 0.4 mL) of air can reduce these artifacts. The volume of air that minimizes this artifact varies slightly for different balloons. The volume can be determined for each balloon by suspending it vertically in water, with the top (proximal end) of the balloon at the surface, allowing it to empty before the tube is closed with a stopcock.⁶⁷

Ppl changes along a vertical gradient, with pressures being most negative at the base of the thoracic space. It is customary to measure pressure in the lower third of the esophagus, to estimate the pressure necessary to expand the greater proportion of the lungs. The balloon is advanced to the gastroesophageal junction (identified easily by the positive pressure caused by an inspiratory sniff) and then pulled back 10 cm.

Having the subject inhale to TLC three times standardizes the volume history and ensures minimization of the changes due to the dynamics of entry of surface-active material into the air-liquid interface. On the third inhalation the subject pauses at TLC for 3 to 5 seconds and then exhales slowly, while flow is interrupted by closing the mouth shutter for 2 to 3 seconds at each of several volumes. Repeating this maneuver four or five times provides enough data to characterize the relationship between the change in lung volume and the change in PL over the entire VC (see Fig. 25-14). To fix the resultant curve on the volume axis requires knowing absolute lung volume at some PL. This is easily measured directly if the curve is obtained with the subject in a body plethysmograph. Alternatively, but less accurately, lung volume (TLC, FRC, or RV) measured at another time by a gas dilution technique, for example, may be assumed to be the same at the time of measurement of lung compliance.

Exponential Analysis. Gibson and Pride⁷⁰ suggested that exponential analysis of the lung pressure-volume curve is superior to other approaches because it is less affected by patient effort and lung size, uses a greater range of the pressure-volume data, and mathematically describes the whole lung^{70a}:

$$V = V_{\max} - Ae^{-KP} \quad (16)$$

where V is the lung volume and V_{\max} is the maximal or extrapolated lung volume at infinite distending pressure. K is a constant describing the shape of the pressure-volume curve.

EXPONENTIAL ANALYSIS OF PRESSURE-VOLUME CURVE. K is related to the incremental compliance (dV/dP) such that

$$\frac{dV}{dP} = AK e^{-KP} = K(V_{\max} - V) \quad (17)$$

where P is the lung elastic recoil pressure. When P is measured in centimeters of water, K has the dimensions of

1/cm H₂O. To describe the curve fully requires the two parameters V_{\max} and A , which both have the dimensions of volume. $A = V_{\max} - V_0$, where V_0 equals the volume extrapolated to $P = 0$. A number of investigators have now used the approach in the evaluation of both restrictive and obstructive ventilatory defects (see later discussion).^{6,70b,70c}

FIBROSIS. Exponential analysis of the pressure-volume curve appears to differentiate restriction due to loss of volume from that due to increased elastic properties.^{70b} Gibson and colleagues^{70b} reported that the elastic properties of the lungs in patients with diffuse interstitial fibrosis can be accounted for almost entirely by a loss of alveoli. This implies that the lungs of such patients consist of a population of completely obliterated, unventilated alveoli and a population of surrounding normal alveoli. Thompson and Colebatch^{70d} confirmed these findings.

EMPHYSEMA. Colebatch and associates³⁰⁹ reported that the constant K (describing the shape of the curve) falls outside the normal range in patients with pulmonary diseases (increased K in emphysema; decreased K in fibrosis). These results were confirmed by others.^{70b}

Other researchers have examined this issue, and the results are more controversial. Gugger and coworkers^{70e} found a significant correlation between elastic recoil pressure and both the FEV₁ and the DL_{CO}. Lung density (measured by CT scans, which, in turn, correlate with the amount of emphysema measured by panel grading) correlated with both the natural logarithm of K and elastic recoil pressure of the lungs at 90% of TLC. Because elastic recoil pressure correlated with emphysema and with FEV₁, their results suggest that loss of elastic recoil is one determinant of airflow limitation in patients with COPD.

Macklem and Eidelman^{70f} and others¹⁶⁵ have reexamined the effect of the elastic properties of emphysematous lungs on airflow obstruction. From published data in normal lungs and in patients with emphysema, they calculated specific lung elastance (change in lung elastic recoil pressure to produce a given fractional change in lung volume) for normal and emphysematous lungs. They found that specific lung elastance and the change in specific elastance with lung elastic recoil were increased in patients with emphysema compared with normal subjects. They speculated that this finding probably represents two distinct abnormalities in the elastic properties of emphysematous lungs: (1) an increase in resting length of alveolar walls, accounting for hyperinflation (TLC); and (2) a decrease in extensibility of alveolar walls once they become stressed (specific lung elastance). Surprisingly, these studies found no correlation between either of these factors and FEV₁. They concluded that the change in elastic properties of the lungs in emphysema does not appear to account for flow limitation in this disease. Furthermore, because of the decreased extensibility of emphysematous lungs, they also suggested that these emphysematous regions are not only poorly perfused but also poorly ventilated; therefore they speculated that emphysema per se may not seriously disturb ventilation-perfusion relationships.^{70f}

An equally surprising study of patients with severe expiratory airflow obstruction was reported by Gelb and colleagues.^{70g} They documented that marked loss of lung elastic recoil, causing hyperinflation with increased TLC, associated with decreased DL_{CO}, can be present despite the absence of or only trivial emphysema on lung CT scans and

in morphologic studies. These authors attributed the decreased DL_{CO} to errors related to inhomogeneity of ventilation and increased physiologic dead space. They attributed the severe, fixed expiratory airflow limitation to intrinsic disease of the bronchioles. They speculated that bronchiolar obstruction caused dynamic hyperinflation and gas trapping, leading to chronic loss of lung elastic recoil through unknown mechanisms, despite the absence of macroscopic emphysema. Thus the combination of increased TLC plus spuriously reduced DL_{CO} may be mistaken for emphysema; in such cases high-resolution lung CT scanning may help to clarify the source of lung hyperinflation as resulting from bronchiolar disease.

Sources of Variability. The ATS has published a formal recommendation on the selection of reference values and interpretative strategies for lung function tests, including FVC, FEV_1 , FEV_1/FVC , FEV_1/VC , and criteria defining a significant response to a bronchodilator for adult white and black men and women.⁶ This statement recommends reference values derived from the *National Health and Nutrition Examination Survey* (NHANES) III, which included whites, blacks, and Mexican Americans.⁷²⁻⁷⁴ In 2010 the Multi-Ethnic Study of Atherosclerosis lung study assessed the performance of the NHANES III reference equations in 3893 participants, of which approximately one third were Asian Americans. This study found the equations to be valid for the previously mentioned ethnic groups and, in addition, the investigators suggested that a correction factor of 0.88 be applied to the predicted and lower limits of normal values when comparing whites and Asian Americans.⁷⁵

The ATS statement also emphasizes the importance of laboratory control of technical sources of variation, including strict adherence to ATS guidelines for equipment performance and calibration, minimizing temperature-related errors, careful validation of computer calculations when purchasing or changing equipment or software, and proper performance of the tests. Although certain within-individual sources of variation fall within the control of each laboratory, between-individual sources of variation are critical to the choice of appropriate reference values. Furthermore, environmental sources of variation pertinent to a given patient (in addition to other relevant clinical data) are likely to be known by the referring clinician. This information should be provided to the laboratory director, who should use it to evaluate the clinical relevance in a given lung function report. When short-term variation

caused by disease, drugs, environment, smoking, laboratory instruments, or submaximal efforts is excluded, body position, head position, effort dependency of maximal flows, and circadian rhythms cause the primary residual sources of variation.⁶ Host factors (e.g., sex, size, aging, race, and past and present health), environmental factors, geographic factors, pollution, and socioeconomic factors cause variability among subjects.

Statistical Considerations. Distributions of FEV_1 and FVC in population studies are close to gaussian in the middle age range but not at the extremes. Furthermore, distributions of flow rates and ratios (FEV_1/FVC) are not symmetrical.²⁸ Therefore publications describing reference populations should include not only the prediction equations but also a means to define their lower limits. A lower limit can be estimated from a regression model. For spirometry, values below the 5th percentile are taken as below the "lower limit of normal."²⁸ If there are sufficient measurements within each category, percentiles can be estimated directly from the data. If the distribution of individual observations is close to gaussian, as it sometimes is in children, the value of the 5th percentile can be approximated.

However, comparisons of spirometric prediction equations indicate that there is good agreement using the 5th percentile. Furthermore, as stated previously, there is no statistical basis for the common practice of using 80% of the predicted normal values for FEV_1 and FVC as the lower limit of normal in adults. For $FEF_{25\%-75\%}$ and for instantaneous airflow rates, this practice causes significant errors because the lower limits of normal for these values are close to 50% of predicted normal values. Using a fixed FEV_1/FVC ratio as a lower limit of normal in adults also causes significant errors because this ratio is inversely related to age and height.²⁸ However, using a fixed percentage of the predicted value as a lower limit of normal may be acceptable in children when the SD is proportional to the predicted mean value. In general, the lowest 5% of the reference populations may be considered as being below the lower limit of normal for any spirometric value.

The ATS suggests that individual laboratories use published reference equations that most closely describe the populations tested in their laboratories. It is useful to compare the results observed in 20 to 40 local subjects with those provided by the intended reference equations. These local subjects should be lifetime nonsmokers selected by age, ethnic group, and sex to match the population usually studied in the laboratory.⁷⁵⁻⁷⁹

yearly changes of 15% or more are probably clinically significant. In a classic epidemiologic study of the changes of FEV₁ over time, normal men were found to have approximately a 40- to 50-mL decrease in FEV₁ per year; the rate of loss increased in smokers, who were susceptible to the damaging effect of cigarette smoke and could return to a normal rate of loss with smoking cessation.^{79a} More recent studies using data from the Framingham Offspring cohort have expanded this analysis to include women, to enlarge the age range, and to standardize the spirometric measurements. In this study, both men and women nonsmokers were found to have an equivalent gradual loss of FEV₁ with age (approximately 20 mL/year in men, 18 mL/year in women).⁸⁰ There was an increase in loss with smoking (38 mL/year in men, 24 mL/year in women) and a benefit from quitting.

Flow-Volume Curves. The range of normal for measurements derived from flow-volume curves has been even more difficult to define than that for spirometry. Correlations with sex, age, and height are poor and do not appear to decrease variability. Most published studies provide prediction equations for mean values only; a few report standard deviation or some other estimate of population variance, but this is of little use in predicting the lower limit of normal. Several investigators have analyzed this problem and have provided predicted mean values and estimates of the lower limit of normal values.^{6,28}

This wide range of normal values limits the interpretation of spirometric and flow-volume curves.⁸¹ If a subject has values in the very low normal range at a given time, the results may be normal for that person or may be significantly abnormal in a person whose VC or flow rates were much higher than average before the onset of the disease. In such cases a discrepancy between static and dynamic measurements, expressed as a percentage of predicted value, may yield a clue to this situation. For example, it would be unusual for a normal person to have a VC that is 115% of the predicted value and a FEF_{25%-75%} that is 85% of the predicted normal value. These findings suggest the possibility of some form of airway obstruction. As with all laboratory tests, evaluation of the results in the clinical context may be helpful in interpretation.

Although the range of predicted values is large, the same pulmonary function tests tend to have reproducibility in the same subject. If variability is limited by careful standardization of pulmonary function testing, spirometry should be reproducible within 5% of the initial values obtained. In addition, if the patients are highly cooperative, the variability can be as small as 2% to 3%.⁸² Thus, repeated measurements of spirometry over time provide a sensitive way of monitoring disease. This reproducibility also accounts for the utility of performing spirometry initially in workers entering a job that will expose them to risks of obstructive or restrictive ventilatory defects.⁸³

Pathophysiologic Patterns

The diagnosis and quantitation of airway obstruction are among the most common uses of pulmonary function tests. RAW, however, is not measured directly by spirometry. Variables derived from spirometry and flow-volume curves may be used to infer increased RAW from measurements of

expiratory airflow achieved with a maximum effort by the subject. Because this maximum effort is not quantitated, the observer can only presume that the decreased flow is due to increased resistance, rather than a decreased effort to produce the flow. If necessary, the degree of effort can be determined using an intraesophageal balloon to estimate pleural pressure or, noninvasively, by estimating compression volume in a pressure-volume plethysmograph (see earlier discussion).

Obstructive Ventilatory Defect. Despite the dependence on effort, reproducible patterns are obtained in normal subjects and in patients with obstructive ventilatory defects (Fig. 25-15). An inference of increased RAW can be made with reasonable assurance, and correlation with measurements made by body plethysmography is good.

In patients with emphysema, most authors suggest that decreased maximal expiratory flow is thought to be due to the effect of loss of lung elastic recoil on airway dimensions, which results in an increased resistance to flow owing to increased compliance and collapse of airway walls.

In emphysema and other diffuse obstructive disorders, the decrease in expiratory flow is usually associated with decreased VC. The decreased VC results from “gas trapping” associated with increased RV. Actual measurement of RV

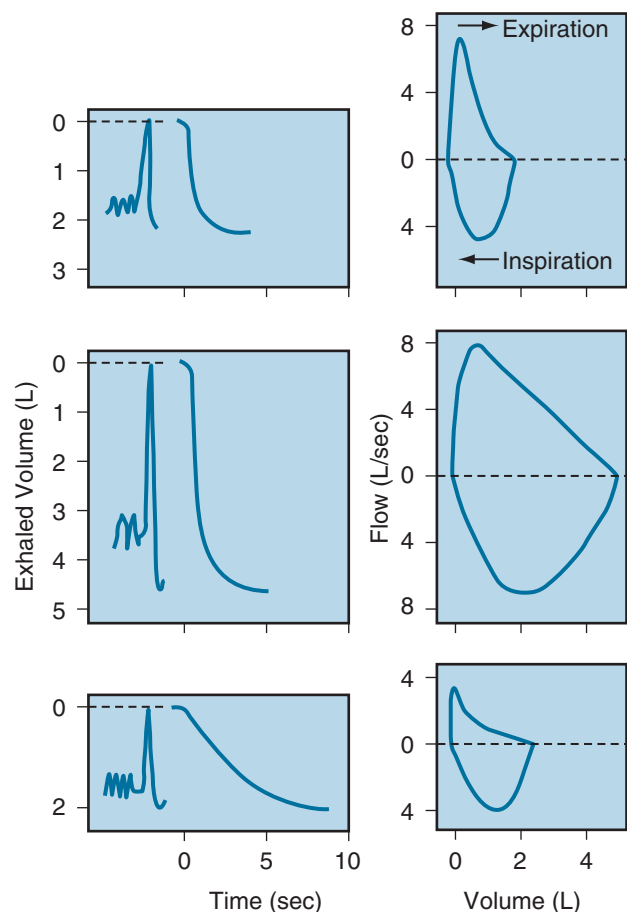

Figure 25-15 The three major patterns of flow. Spirograms and flow-volume curves are shown which were obtained in a patient with a restrictive ventilatory defect (*top*), a normal subject (*middle*), and a patient with an obstructive ventilatory defect (*bottom*).

may be necessary to document this phenomenon and to rule out a mixed restrictive and obstructive ventilatory defect. Expressed as percentages of predicted values, the decrease in VC in patients with obstructive ventilatory defects is relatively less severe than the decrease in airflow.

The pulmonary ventilation is limited ultimately by the highest flows that can be generated by the subject. Even during high-intensity exercise, most healthy subjects do not experience expiratory flow limitation.⁸⁴ However, patients with COPD may experience expiratory flow limitation at low work rates during exercise or even at rest, as first suggested by Potter and colleagues.⁸⁴ Potter's group reported that patients with advanced COPD often breathe on their maximal expiratory flow-volume curves during tidal breathing. They suggested that this phenomenon develops because of expiratory flow limitation (i.e., inability to increase flow beyond a limit at a given lung volume). The phenomenon of expiratory flow limitation has been studied extensively in COPD patients both at rest and during exercise.^{85,86} Flows observed during tidal breathing in COPD patients often exceed the maximal expiratory flow-volume envelope.^{84,85} This pattern has been termed "negative-effort dependence" and is attributed to abnormal compressibility or collapse of the airway walls; in this situation, tidal breathing involves less expiratory force, less collapse of highly collapsible airways, and slightly greater flow than seen with a maximal forced expiratory maneuver.

Restrictive Ventilatory Defects. A restrictive ventilatory defect is suggested by a decreased VC, reflecting limitation in chest excursion (which, according to the ATS expert panel, requires confirmation by a decreased TLC). Typical results consist of a decreased VC, little or no reduction in expiratory airflow, and relative preservation of MVV. Early in the development of an interstitial lung disease, before development of decreased lung volumes, *volume-corrected* flow (i.e., flow divided by the total lung capacity, to account for lung size) and FEV₁/FVC ratios are increased. These increased airflow rates result from the increased force causing outward traction on airway walls. Thus airway diameters become larger than normal relative to lung volume, so airflow rates are increased. Because of the increased flows relative to lung volume, the usual flow-volume curve in restrictive defects is tall and narrow (see Fig. 25-15). With time, as the disease becomes more severe, lung volumes decrease, as reflected by a decreased VC. If the disease can be reversed, volumes return to normal first, then volume-corrected flows, and then the FEV₁/FVC ratio.⁹⁸⁻¹⁰⁰

DISTRIBUTION OF VENTILATION

For discussion of ventilation, blood flow, and gas exchange, see Chapter 4

Tests that measure distribution of ventilation are very sensitive to abnormalities in lung structure and function but are nonspecific. Thus they are useful for detecting the presence of abnormal function early, when other test results are normal, or to confirm the presence of airflow obstruction when other test results are only mildly abnormal. They are particularly important in the evaluation of patients

with suspected upper airway obstruction to determine if there is associated disease of the airways distal to the trachea. They may be very useful in epidemiologic studies, such as evaluation of the effects of smoking or air pollution in large populations.

MEASUREMENTS OF DISTRIBUTION OF VENTILATION

The physiologic determinants of distribution of ventilation are reviewed in Chapter 4. eFigure 25-9 illustrates the concept of uneven distribution of inspired gas.

Resident Gas, Single-Breath Test

The single-breath nitrogen washout test (sometimes called the single-breath oxygen test) is designed to assess the uniformity of gas distribution in the lungs and the behavior of the dependent airways.¹⁰¹ At present, the most clinically useful aspect of the test is the measurement of the slope of phase III (alveolar gas plateau) to determine the uniformity of gas distribution.

A lung clearance index can be measured not only by resident N₂ but also by exogenous tracer gas using a mass spectrometer or, more recently, a novel gas analyzer (Innocor), thus providing a potentially useful clinical tool as an early marker for disease in children and adults.¹¹⁰ With the use of exogenous tracer gases not found in normal air, patients can perform the washout tests while breathing air and not pure oxygen, as is needed for nitrogen washout. By breathing air, the patient avoids the unwanted changes in ventilation related to oxygen breathing. Sulfur hexafluoride, an inert gas, is a tracer used for this purpose.¹¹¹

CLINICAL APPLICATIONS

Tests of distribution of ventilation have been used widely in epidemiologic studies. Studies of cigarette smokers and studies of patients with mild airway obstruction have suggested that the single-breath nitrogen washout test (phase III) often has the most abnormal test results of lung function, and sometimes the only abnormal test results. The sensitivity of these tests of distribution may also prove useful in the field of occupational health for early detection of the effects of occupational hazards, but the practical value of these tests for occupational screening remains to be established.

The usefulness of tests of distribution of ventilation in clinical evaluation is well established. The single-breath nitrogen washout test has abnormal results in both restrictive and obstructive ventilatory defects. Presumably, this reflects its sensitivity to abnormalities in the mechanical properties of the lungs. Even though interstitial pulmonary fibrosis or emphysema may affect the lung diffusely, the process is never distributed homogeneously. Thus some regions of lung fill and empty more slowly than others, resulting in abnormal single-breath nitrogen test results. Why, then, is a test of distribution indicated in clinical evaluations? First, in mild disease, spirometry and clinical evidence may be equivocal, but tests of distribution may provide a more sensitive indicator of the presence of disease and the response to treatment. Second, not only is the test sensitive, but the degree of abnormality of the single-breath

Expiratory Flow Limitation Assessed by Comparison of Tidal and Maximal Flow-Volume Curves

1. Tidal and maximal flow curves are usually aligned on the assumption that TLC does not change during exercise and hence that changes in inspiratory capacity reflect changes in end-expiratory lung volume. Most reports indicate that TLC does not change with exercise,^{86,87} but others have found that TLC does increase.⁸⁸ In addition, this approach assumes that the patients can make a truly maximal inspiratory effort during exercise. In fact, some COPD patients are not able to perform these maneuvers during exercise.
2. Maximal expiratory airflow depends on the volume and time history of the preceding inspiration.^{89,90} However, the previous volume and time history always differ between tidal breathing and maximal inspiration. Therefore assessment of flow limitation by comparison of tidal and maximal flow-volume curves may lead to erroneous assumption of abnormal airway collapsibility, even if the measurements are made plethysmographically.
3. In nearly all reports, the tidal and forced flow-volume loops were obtained from measurements of expired gas volume at the mouth. The assumption is made that both loops develop at the same lung volume when, in fact, the forced loop may be at a smaller volume due to gas compression during the forced maneuver. Such gas compression artifacts can be avoided by measuring volume with a body plethysmograph, as suggested by Ingram and Schilder.⁹¹
4. Exercise may result in bronchodilation and other changes in the mechanical properties of the lungs, which may affect both the tidal and maximal flow-volume curves.⁸⁶
5. Evaluation of expiratory flow limitation has also been studied by comparison of tidal flow-volume curves with partial flow-volume curves, thereby keeping the previous volume history constant. Although theoretically appealing, this approach often neglects the effect of the previous time history (which affects both partial and maximal forced flow-volume curves)^{89,92} and is not practical in most patients with COPD at rest, let alone during exercise.

Thus it appears that study of expiratory flow limitation on the basis of comparison of tidal with maximal flow-volume curves can be problematic. An alternative approach, called the negative expiratory pressure method, has been developed by Koulouris and associates⁹³ (eFig. 25-8). This method does not require flow-volume maneuvers by the subject, nor must it be performed in a body plethysmograph. A negative pressure is applied at the mouth during a tidal expiration, and the ensuing expiratory flow-volume curve is compared with that of the previous control tidal expiration. With this method the volume and time history of the control and test breath are the same. The negative expiratory pressure method has been validated in mechanically ventilated patients by direct comparison with isovolume pressure-flow curves.⁹⁴ It has also been used to study stable COPD patients at rest and during exercise.^{95,96}

Ninane and associates⁹⁷ have offered another approach to the technical issues associated with comparing tidal breathing with maximal flow curves. They described a

method to detect expiratory flow limitation by manual compression of the abdominal wall. In healthy subjects, abdominal compression causes decreased abdominal diameter, increased gastric and pleural pressures, and increased expiratory flow. This method has been used successfully to study expiratory flow limitation in neonates, but in adults with COPD abdominal compression fails to increase expiratory flow despite increased gastric and pleural pressures.⁹⁷

Protocol. The single-breath nitrogen washout test (sometimes called the single-breath oxygen test) is designed to assess the uniformity of gas distribution in the lungs and the behavior of the dependent airways.¹⁰¹ At present the most clinically useful aspect of the test is the measurement of the slope of phase III (alveolar gas plateau) to determine the uniformity of gas distribution. The subject inspires a single breath of pure oxygen from RV to TLC (inspiratory VC maneuver); nitrogen concentration at the mouth during exhalation is measured with a nitrogen analyzer or mass spectrometer. At end-inspiration, the dead space is filled with oxygen that has just been inspired (see eFig. 25-9). At the beginning of the subsequent expiratory VC maneuver, the nitrogen meter continues to record 0% nitrogen, because the first gas to leave the lungs is from conducting airways—the so-called anatomic dead space (phase I) (see eFig. 25-9). Subsequently, the nitrogen concentration increases in a sigmoid curve upward and reflects mixing of gas from dead space and alveoli (phase II). The slightly sloping plateau in phase III reflects the almost constant nitrogen concentration in alveolar gas. If inspired oxygen is distributed evenly to all alveoli so each has the same nitrogen concentration, then phase III of the nitrogen tracing is almost horizontal (alveolar plateau). However, if inspired oxygen is distributed unevenly (as happens to a small extent even in healthy subjects), then the end-inspiratory nitrogen concentrations are not equal throughout the lung. The concentrations of exhaled nitrogen from different alveoli are not recorded as a horizontal line; the first portion of phase III usually contains a lower nitrogen concentration than the last portion.

The analysis of these curves is not entirely objective. When the same observer reads such curves twice under “blind” conditions, agreement between the two measurements is poor. This variability appears to be due to differences between individual lungs; when a subject generates such a curve, usually all curves produced by that subject are difficult to analyze. On the other hand, if a subject generates a curve that is easy to analyze, most curves produced by that subject are reproducible. Obviously, analysis of these curves requires good judgment; some curves, although conforming to the criteria of acceptability, are unreadable and therefore should be ignored. It appears difficult, if not impossible, at present to establish a uniform set of criteria for this analysis.¹⁰²

Normal Values. The slope of phase III (percentage of nitrogen per liter) is determined as the line of best fit (by least-squares linear regression) between 70% of VC and the onset of phase IV. In most cases, the range about the mean of three measurements of the slope of phase III should not be greater than $\pm 0.5\%$ N₂/L.¹⁰³ The variations appear to be independent of the time of day at which the test is

performed, but the slope of phase III does depend on inspiratory flow.¹⁰⁴

The TLC measured by the single-breath nitrogen test correlates well with that measured by helium dilution in a population of men and women free from abnormalities of gas distribution, for both smokers and nonsmokers with and without symptoms.¹⁰³ As expected, the measurement of TLC underestimates lung volume in patients with airway obstruction.^{6,103}

Other Tests

The methods just described use the resident-gas technique. Similar measurements made by bolus techniques and resident-gas techniques have been compared, and they show either close similarities in results or a systematic tendency for measurements of phase IV determined by the resident-gas technique to be slightly lower than those determined by the bolus technique.¹⁰⁵

Other methods used to assess uniformity of distribution of ventilation include measurement of residual nitrogen following multiple-breath, open-circuit nitrogen washout¹⁰⁶ and determination of helium mixing time during closed-circuit equilibration. In the multiple-breath nitrogen washout, for example, continuous breath-by-breath measurement of nitrogen concentration at the mouth during tidal breathing of pure oxygen is performed until end-tidal nitrogen concentration falls to less than 1%. The fall in end-tidal nitrogen concentration on a breath-by-breath basis is

related to the cumulative volume of ventilation or breath number. By extending the nitrogen washout time to 30 minutes or more in subjects with severe chronic airway obstruction, estimates of lung volume may be obtained that compare favorably with those calculated by plethysmographic or radiographic methods.¹⁰⁷

Exponential analysis of the end-tidal nitrogen concentration with time, cumulative ventilation, or breath number reveals that in normal subjects nitrogen concentration decreases in a single exponential curve. In the presence of uneven distribution of ventilation, the curve can be described by two or more exponentials. This analysis can be extended to estimate the size of poorly ventilated regions of the lung, but these multiple-breath tests are cumbersome and time-consuming, may have no anatomic correlates, and cannot be repeated rapidly (i.e., until all the added oxygen is washed out).

With the advent of rapidly acting infrared analyzers in commercial pulmonary function equipment, in which various filters are used in conjunction with an infrared analyzer to analyze methane, carbon monoxide, and acetylene to measure diffusing capacity and pulmonary blood flow, the opportunity has developed to assess distribution of ventilation using added inert gases, such as methane. The principle is the same as that for resident gases, but the modeling and mathematics are slightly altered. Reference equations have been published for values expected in healthy normal subjects.^{108,109}

nitrogen washout test results is generally proportional to the amount of underlying lung disease. Third, the degree of abnormality of the test results may give an indication of the difficulties to be expected in gas exchange. When the closing volume (phase IV) is elevated above FRC, it is likely to be associated with atelectasis and hypoxia, particularly when narcotics or hypnotic drugs depress the drive to ventilation. Finally, in patients with suspected upper airway obstruction, a test of distribution of ventilation (e.g., single-breath nitrogen washout) may be the only way to assess whether there is associated disease of the airways distal to the carina.

DIFFUSION

Physiologists have devised a variety of methods to study the diffusion of gases across the alveolar-capillary membranes; many of these methods are useful clinically, and their physiologic foundations are discussed in Chapter 4. The advantages of physiologic tests for measuring diffusing capacity are that they permit diagnosis of an impaired surface area for the transfer of gases from the alveoli to the pulmonary capillaries, sometimes even during early stages of disease. Many pulmonary diseases are manifested by a diffusion defect when there is no abnormality apparent in other routine pulmonary function tests. These diseases include all interstitial lung diseases, asbestosis, scleroderma, lupus erythematosus, emphysema, pulmonary thromboembolism, diffuse metastatic cancer of the lungs,¹¹² *Pneumocystis jirovecii* pneumonia, and rejection of a transplanted lung. There is now considerable evidence correlating the diffusing capacity and its subdivisions (*membrane diffusing capacity* [DM] and *pulmonary capillary blood volume* [VC]) with the morphometric study of normal lungs.¹¹³ Similar correlative studies of the lungs of patients with emphysema⁴⁸ document the structural basis for the abnormal alveolar-capillary interface as a result of decreased numbers of patent pulmonary capillary segments.¹¹⁴ Finally, the tests are relatively simple (as far as the patient is concerned) and easy to repeat, making it practical to study the diffusing capacity frequently and to evaluate the effects of therapy or the natural history of the disease.

MEASUREMENTS OF PULMONARY DIFFUSING CAPACITY (TRANSFER FACTOR)

General Principles

The measurement of pulmonary *diffusing capacity* (also known as *transfer factor*) requires the use of a gas that is more soluble in blood than in lung tissues. Oxygen and carbon monoxide are the only two such gases known, and their chemical reaction with hemoglobin is responsible for this unusual pattern of “solubility.” Both molecules measure the same process, and estimates of DL_{O_2} can be made by multiplying the DL_{CO} by 1.23. However, the more difficult and time-consuming method of measurement by oxygen has been largely displaced by the carbon monoxide method.

For the standard DL_{CO} method, a low concentration of carbon monoxide is delivered to the lungs by adding about 0.3% carbon monoxide to inspired air. The mixed venous carbon monoxide concentration is assumed to be zero for

all practical purposes (unless the test is repeated frequently over a short time). Molecules of carbon monoxide diffuse across the membrane, dissolve in the plasma, and then combine with hemoglobin. Carbon monoxide has a high affinity for hemoglobin, 210 times that of oxygen; thus carbon monoxide in the vicinity of a hemoglobin molecule binds avidly to it, and the partial pressure of dissolved carbon monoxide remains very low. Except in a patient with severe anemia, the available binding sites for carbon monoxide are so numerous that they cannot be saturated by the number of carbon monoxide molecules that diffuse from the air spaces to the capillary blood at the low concentrations of carbon monoxide used in the test. Therefore carbon monoxide transfer is not limited by pulmonary blood flow; instead, it is limited primarily by the alveolar-capillary diffusion rate and, to a lesser extent, by the red blood cell membrane diffusion rate and the chemical reaction rate between hemoglobin and carbon monoxide. The carbon monoxide transfer therefore can be considered a measure of the capillary surface area available for gas exchange.

In contrast, gases such as Freon, nitrous oxide, and acetylene are equally soluble in lung tissues and blood because they do not combine chemically with blood components. These gases diffuse across the alveolar-capillary membranes and quickly saturate the plasma; further diffusion is prevented until fresh blood enters the pulmonary capillaries. Thus these gases can be used to estimate pulmonary capillary blood flow to ventilated lung units.

There are some important differences in the transfer of carbon monoxide and oxygen. Both plasma and hemoglobin contain oxygen (but not carbon monoxide) when mixed venous blood enters the pulmonary capillaries. The rate of oxygen diffusion into blood depends on the alveolar-capillary PO_2 difference. As oxygen crosses the alveolar-capillary membranes, capillary PO_2 increases, narrows the alveolar-capillary PO_2 difference, and slows diffusion. Thus, before calculating a diffusing capacity for oxygen, blood PO_2 must be known at every point along the capillary and can be obtained by a combination of certain measurements and mathematical computations.¹¹⁵

Carbon Monoxide Methods for Clinical Measurement of Pulmonary Diffusing Capacity. The DL_{CO} is calculated as follows:

$$DL_{CO} = \frac{\text{CO transferred from alveolar gas to blood (mL/min)}}{\text{Mean alveolar CO pressure} - \text{Mean capillary CO pressure (mm Hg)}} \quad (18)$$

To determine the amount of carbon monoxide transferred from alveolar gas to blood per minute, it is necessary to measure the mean alveolar carbon monoxide pressure and the mean pulmonary capillary carbon monoxide pressure. There are several tests available.

The *standard single-breath* DL_{CO} test is probably the most widely used and the best standardized of the various methods described. It has been used in the largest number of normal subjects and has been corrected for the effects of age, body size, sex, ethnic background, cigarette smoking, and physiologic factors.

The *intra-breath* method requires a special, very rapid infrared analyzer, but this is also commercially available. Because this method does not require a breath-hold and

expiratory flow can be controlled by a critical orifice, the intrabreath method is probably the easiest of the four methods for sick patients to perform. With proper filters the same analyzer can be used to measure methane, acetylene, and carbon monoxide simultaneously. Diffusing capacity can be measured during exercise to define distensibility of the capillary bed using the intrabreath or three-gas iteration method, but this also requires extensive validation and establishment of predicted normal values.¹¹⁶⁻¹¹⁸

The *three-gas iteration* method may be more reproducible and is unaffected by a wide variety of factors that alter the single-breath or intrabreath methods, especially abnormalities in distribution of ventilation. More normal data are needed, as is validation in other laboratories, but the method is commercially available.

The *steady-state*, or rebreathing method, can also be measured during exercise, but is not widely used because its results are markedly affected by uneven distribution of ventilation or ventilation-perfusion abnormalities. The rebreathing method is more variable than the single-breath method and requires considerable patient cooperation to attain the rapid respiratory rate required.

SINGLE-BREATH METHOD. In the single-breath method, the patient inhales a gas mixture containing 0.3% carbon monoxide and a low concentration of inert gas (0.3% neon, 0.3% methane, or 10% helium), then holds his or her breath for approximately 10 seconds. During the breath-hold, carbon monoxide leaves the air spaces and enters the blood. The larger the diffusing capacity, the greater the amount of carbon monoxide that enters the blood in 10 seconds.

The equation used in the single-breath method is as follows:

$$DL_{CO} = \frac{V_A \times 60}{(P_{bar} - 47) \times t} \ln \frac{F_{ACO_0}}{F_{ACO_t}} \quad (19)$$

where F_{ACO_t} is *fractional alveolar carbon monoxide concentration* at time (t), t is breath-hold time in seconds, P_{bar} is *barometric pressure* (in mm Hg), V_A is *alveolar volume* (in mL) obtained from the ratio of inspired and expired inert gas concentrations and inspired volume, F_{ACO_0} is the inspired carbon monoxide concentration corrected for dilution by the RV as estimated by the ratio of inspired and expired inert gas concentrations, and 60 is the conversion factor for seconds to minutes.

In the single-breath test, alveolar PCO is not maintained at a constant concentration, because carbon monoxide is absorbed during the period of breath-holding. Furthermore, the mean alveolar PCO is not the average of the PCO at the beginning and end of the breath-holding period. However, the mean alveolar PCO can be estimated and diffusing capacity measured. The single-breath test requires little time or cooperation from the patient except to inhale and to hold the breath for 10 seconds. Analyses are performed with an infrared analyzer or gas chromatograph, and no blood samples are needed. The test can be repeated a number of times rapidly, if desired. However, a measurement of the patient's RV is required, because a value for total alveolar volume during breath-holding must be calculated to measure carbon monoxide uptake. Furthermore, an inert gas such as helium, methane, or neon must be inhaled with carbon monoxide to correct for dilution of inspired

carbon monoxide. This method has the disadvantages that carbon monoxide is a nonphysiologic gas, breath-holding is not a normal pattern of breathing, and breath-holding for 10 seconds may not be possible for patients with severe dyspnea or during exercise.

Factors such as inhalation time, breath-holding time, breath-holding lung volume, exhalation time, and the size and portion of alveolar gas sampled have all been shown to affect the single-breath DL_{CO} . Ogilvie and colleagues¹¹⁹ recognized that these discrepancies could exist either because diffusing capacity is not distributed homogeneously within the lung or because the single-breath equation ignores the fact that carbon monoxide uptake takes place during inhalation and exhalation as well as during breath-holding. They tried to circumvent these problems by standardizing the test.

Jones and Mead¹²⁰ showed that, because the diffusion equation was valid only for breath-holding, there are errors in calculation of single-breath DL_{CO} owing to the nature of carbon monoxide uptake during inhalation and exhalation. Because delay in collection of the alveolar sample has been shown to cause an apparent increase in DL_{CO} , the ATS epidemiology standardization project²³ developed a variation of the Jones and Mead method that took this problem into account and placed strong emphasis on an automated system, which standardized the procedure and is available in most modern commercial systems.

INTRABREATH METHOD. In the intrabreath (within-breath or exhaled) DL_{CO} method, DL_{CO} is measured at increments of the exhaled volume using a method devised by Newth and associates¹²⁷ and modified by Hallenborg and colleagues.¹²⁸

Although more complicated than the standard single-breath method, this technique makes no assumptions about the initiation of carbon monoxide uptake or the volume at which carbon monoxide uptake manifested, measures carbon monoxide uptake directly during the entire maneuver, and can be used during exercise as well as at rest. The method does require a rapidly responding carbon monoxide meter or special modification of a mass spectrometer (to measure $C^{18}O$) to make the number of measurements of carbon monoxide concentration required during the single exhalation. The intrabreath method has been useful in detecting pulmonary hemorrhage¹²⁸ and pulmonary vascular obstruction.¹³⁰ The method is now available commercially using a rapidly responding infrared analyzer. With appropriate filters, the device can measure not only carbon monoxide but also methane (to measure tracer gas dilution) and acetylene (to measure pulmonary capillary blood flow to ventilated lung units), and the response to all three gases is linear.^{109,131-133}

Indications

The diffusing capacity is affected by those physiologic and pathophysiologic conditions that change the surface area of pulmonary capillaries available for gas exchange. For most purposes, one can think of DL_{CO} as a measure of the blood-filled capillaries in the lung.

It is interesting to consider the conditions that can increase the DL_{CO} . Indeed, many processes can increase the capillary blood surface area by increasing the blood volume in the lung, including recumbent posture, pregnancy, and obesity. Many pathologic processes that do not involve lung disease

Diffusing Capacity

STEADY-STATE METHOD. In the steady-state method, the patient breathes a mixture of 0.1% carbon monoxide in air for several minutes through a one-way valve system. During the last 2 minutes, exhaled gas is collected in a plastic bag and analyzed for oxygen, carbon dioxide, and carbon monoxide concentrations (requiring rapidly responding gas analyzers). During collection, an arterial blood sample is drawn and analyzed for PCO_2 .¹²¹ The amount of carbon monoxide transferred from the air spaces to capillary blood per minute ($\dot{V}CO$) can be calculated from the inspired and expired gas concentrations and the volume of gas exhaled ($\dot{V}E$) at standard conditions (i.e., STPD, where the “ideal gas” is corrected to standard pressure dry [760 – 47 mm Hg] and 0°C or 273°K, where 1 mole of ideal gas occupies 22.4 L.). The mean alveolar fractional concentration of carbon monoxide (FACO) is estimated from the Bohr equation for dead space volume divided by tidal volume (V_D/V_T). Assuming that V_D/V_T for carbon dioxide and carbon monoxide are the same, FACO can be calculated with the following equation, using the fractional concentrations of mixed expired carbon monoxide (FECO), mixed expired carbon dioxide (FECO₂), alveolar carbon dioxide (FACO₂), and inspired carbon monoxide (FICO):

$$FACO = FICO - \frac{FACO_2(FICO - FECO)}{FECO_2} \quad (20)$$

$$PACO = FACO(Pbar - 47) \quad (21)$$

This value (alveolar carbon monoxide [PACO]) can now be used to calculate pulmonary diffusing capacity:

$$DL_{CO} = \frac{\dot{V}CO}{PACO} \quad (22)$$

Steady-state DL_{CO} can be measured during tidal breathing, anesthesia, sleep, and exercise. Nevertheless, the method is not used widely because its results are more subject to error than those of the single-breath technique, especially in patients with uneven distribution of ventilation or with ventilation-perfusion abnormalities. In these conditions, a decreased DL_{CO} (steady state) may reflect impairment of the ventilation-perfusion ratio $\dot{V}A/\dot{Q}C$, where $\dot{V}A$ is alveolar ventilation and $\dot{Q}C$ is pulmonary capillary blood flow, or an alteration of pulmonary gas transfer. A major problem is the estimation of alveolar carbon monoxide concentration. In addition, the method requires obtaining an arterial blood sample and is extremely sensitive to changes in breathing pattern. The “end-tidal” modification¹¹² of the steady-state method does not require arterial blood samples but suffers from even more sources of error. Both approaches to the estimation of diffusing capacity really reflect ventilation-perfusion abnormalities in the lungs more than characteristics of the alveolar-capillary surface and functioning pulmonary capillaries. Marshall¹²² has reported another modification of this method, in which mixed venous PCO_2 was computed by an equilibration method that avoids arterial puncture but may be too imprecise for use in the Filley equations (Equations 21 and 22) at rest.

REBREATHING METHOD. In the rebreathing method,¹²³ the patient rebreathes the test gas (air plus a low concentration of carbon monoxide) from a reservoir, the volume of which equals the patient's FEV₁. The patient exhales to RV before a valve is turned, then rebreathes from the reservoir, which should be emptied with each inspiration. Rebreathing

continues for 30 to 45 seconds at a controlled rate of 30 breaths/min (to ensure mixing between lung and reservoir). The volume of RV plus reservoir, multiplied by the change in carbon monoxide concentration, equals the carbon monoxide volume transferred. Mean capillary PCO is neglected. Mean alveolar PCO is calculated from the same equation used in the single-breath method. The rebreathing method for measuring DL_{CO} is more variable and requires considerable patient cooperation, but it is less influenced by abnormalities in distribution of ventilation and is easier to use during exercise than the steady-state or single-breath technique. The rapid respiratory rate may be difficult for some patients to maintain and is not physiologic.

THREE-GAS ITERATION METHOD. Graham and associates¹²⁴ have described a method of calculating DL_{CO} that uses separate equations for the inhalation, breath-hold, and exhalation phases of the single-breath maneuver rather than trying to force them to fit the breath-hold equation. The method is now available commercially using a rapidly responding infrared analyzer. This method has been reported in a theoretical paper,¹²⁵ analyzed in a lung model, and compared with the standard Ogilvie method,¹¹⁹ the Jones-Mead modification,¹²⁰ and the ATS epidemiology standardization modification of the Ogilvie method.²³ It has also been reported during exercise.¹¹⁶⁻¹¹⁸

Although DL_{CO} values calculated using the three conventional methods showed large changes with variations in inspiratory flow rates, inspiratory volumes, and collection times, the three-equation method yielded calculations of DL_{CO} that were minimally affected by these changes.¹²⁴ These results agree with previous results obtained in the lung model, support the hypothesis that diffusing capacity is independent of lung volume, and indicate that the three-gas iteration method significantly improves the accuracy and precision of single-breath measurements.¹²⁶

PROTOCOL. As originally described, the subject performs two VC maneuvers, then exhales to RV and rapidly inhales a mixture containing 0.3% carbon monoxide, 15% helium, 21% oxygen, and the remainder nitrogen from a bag-in-box. After a 3-second breath-hold, the subject exhales while watching a flow signal to maintain a constant flow of 0.5 L/sec. Carbon monoxide concentrations are measured continuously with a rapidly responding infrared meter, and helium concentrations are measured with a mass spectrometer. Airflow is measured with a pneumotachygraph and integrated electrically to obtain volume. Data are converted from analog to digital form at 30 points per second and recorded by a digital computer to adjust carbon monoxide and helium recordings for time lags and to remove cardiac oscillations using a sliding, 30-point curve-averaging technique. The exhaled VC is divided into 2% decrements, and the corresponding exhaled carbon monoxide and helium values are used for calculations. The initial part of the VC, until the onset of phase III of the helium curve, is discarded as dead space. The lower portion of the VC, after the onset of phase IV of the helium curve, is also discarded because of uncertainties regarding contributions by dependent regions to expired gas concentrations. Approximately 40 data points are obtained over the lower 80% of the exhaled VC, and the rate of carbon monoxide uptake is calculated over 10% intervals of the exhaled VC (e.g., 20% to

30%, 22% to 32%). Alveolar volume is calculated at the midpoint of each 10% interval by subtracting the exhaled volume from TLC (measured by the single-breath helium

dilution method). Intradbreath DL_{CO} is calculated in each interval by the Krogh equation¹²⁹ and plotted against exhaled volume.

can also increase blood volume in the lung, such as congestive heart failure. Lung diseases that can increase blood volume are thought to include asthma, perhaps by increased intrathoracic negative pressures, and diffuse alveolar hemorrhage.

Most pathologic processes that involve the pulmonary capillaries *decrease* the DL_{CO} . Therefore the most common clinical indications for measuring DL_{CO} include evaluation of patients with diffuse interstitial lesions such as sarcoidosis and asbestosis,¹³⁴ evaluation of patients suspected of having emphysema, for which several structure-function studies are now available,⁴⁸ and assessment of patients with pulmonary vascular obstruction.¹³⁵ It is important to recognize that the DL_{CO} depends on hemoglobin concentration; decreased DL_{CO} caused by severe anemia must not be misinterpreted as secondary to nonexistent lung disease. Thus DL_{CO} is routinely corrected for hemoglobin concentration, if known.

Standardization of the Single-Breath Methods

The ATS has recommended standardization of the test using criteria including rapid inspiration, inspired volume at least 90% of largest VC, breath-hold time between 9 and 11 seconds, and adequate washout and sample volumes. The mean of the acceptable tests is reported; if more than two tests are performed, the mean of all acceptable tests is reported. Calculations are standardized for breath-hold time and adjusted for dead space, gas collection conditions, and carbon dioxide concentration. Reproducibility of the two acceptable tests should be within 10% or 3 mL/min per mm Hg (at *standard temperature, pressure, and dry* [conditions] [STPD]), whichever is larger. When the ratio of DL_{CO} to alveolar volume (DL_{CO}/VA) is reported, DL_{CO} is at STPD and VA is at BTPS.

Interpretation

Subdivisions of the Total Diffusing Capacity. It is possible to separate the pulmonary diffusing capacity into its two components: the *membrane diffusing capacity* (DM) and the component related to the pulmonary capillaries (Vc). Nonetheless, it has been shown that almost all decreases in diffusing capacity are due to decreases in the capillary component (Vc).

$$1/DL_{CO} = 1/\theta VC + 1/DM \quad (31)$$

The method of separation depends on measurement of DL_{CO} at different alveolar oxygen pressures. When alveolar oxygen is increased by breathing enriched oxygen mixtures, oxygen molecules compete with carbon monoxide molecules for reactive sites on hemoglobin, thereby decreasing carbon monoxide uptake by the red blood cells. However, even at the higher oxygen concentration, transfer of carbon monoxide across the alveolar-capillary membranes is presumed to be unaffected. Thus measurements of DL_{CO} at 21% oxygen and at several higher concentrations of oxygen permit separation of the two components of the DL_{CO} (eFig. 25-11).¹⁵⁰

Diffusing Capacity for Nitric Oxide

The *diffusing capacity of the lung for nitric oxide* (DL_{NO}) is a relatively new pulmonary function test and similar in many ways to the more established DL_{CO} .¹⁵¹ It differs from the

latter in being independent of P_{O_2} and the hematocrit. It has been suggested that DL_{NO} can be used to describe pulmonary DM directly.^{151a}

CLINICAL APPLICATIONS

The single-breath DL_{CO} can be used to differentiate airflow obstruction associated with intrinsic airway disorders from obstruction related to emphysema. A normal single-breath diffusing capacity in the setting of an obstructive pattern argues against the presence of emphysema.⁴⁸ In fact, a normal or increased single-breath DL_{CO} associated with airflow obstruction is often associated with asthma.¹⁶⁰ The single-breath DL_{CO} may be abnormal in patients with emphysema when there is no evidence of airflow obstruction, and it may become progressively more abnormal much more rapidly than tests of airway function, even when they do become abnormal.¹⁶¹ Several studies have demonstrated a correlation not only with the presence of emphysema but also with the amount of emphysema.^{134,162-165}

DL_{CO} has also been used to study the earliest stages of emphysema. For example, some studies suggest that alveolar septal destruction may be seen in cigarette smokers before the development of either increased air space size or anatomic evidence of emphysema.¹⁶⁶ In our laboratory, single-breath DL_{CO} was found to correlate with emphysema grade by panel grading¹⁶⁷ from grade 1 to 100 ($r = -0.73$) in 50 patients whose lungs were studied at surgical resection, which was performed within 1 week of their pulmonary function tests (eFig. 25-12). However, for the milder, early emphysema at grade 30 or less, the intrabreath DL_{CO} appeared to be more sensitive and specific than the single-breath DL_{CO} .¹²⁷

Pulmonary Vascular Obstruction

The changes in DL_{CO} in the setting of pulmonary vascular obstruction can be complex, making it difficult to make a straightforward diagnosis. If pulmonary *capillaries* are occluded, single-breath DL_{CO} is decreased.¹¹⁴ In the presence of *precapillary* vascular obstruction, with the obstruction upstream of the capillaries, the single-breath DL_{CO} may be decreased,¹⁶⁸ normal,¹⁶⁹ or even increased, depending on the effect on pulmonary capillary blood volume. The capillary blood volume in turn depends on the relationship between pulmonary arterial pressure, pulmonary venous pressure (or left atrial pressure), and bronchial collateral blood flow. For example, bronchial arterial pressure may distend capillaries via collateral channels so that, even if pulmonary arteries are obstructed, a normal DL_{CO} may be maintained. In our laboratory, every patient with pulmonary vascular obstruction who had decreased single-breath DL_{CO} had a decreased pulmonary capillary blood volume.

Finally, capillary distention may vary in different parts of the lung (Fig. 25-16). According to the model of the zones of lung perfusion presented by West and colleagues,¹⁷⁰ at the lower zone at the lung base, capillaries are distended by pulmonary arterial and pulmonary venous pressures. Even if the pulmonary arteries are obstructed, the capillaries are distended by pulmonary venous pressure and the DL_{CO} is maintained. DL_{CO} is decreased in this zone if the capillaries are occluded or if pulmonary venous pressure is decreased.

Interpretation of Diffusing Capacity

HEMOGLOBIN. Adjustment for hemoglobin is not mandatory but is desirable. Unadjusted values must always be reported even if the adjusted values are also reported. The adjustment should be made on the observed, not the predicted, value. Hemoglobin is reported in grams per deciliter, and the method of Cotes and associates¹³⁶ should be used to make the adjustment:

$$\text{Hemoglobin-adjusted } DL_{CO} = \text{measured } DL_{CO} \times \frac{(14.6 \times DM/Vc) + \text{hemoglobin}}{\text{hemoglobin} \times (1 + DM/Vc)} \quad (23)$$

where DM is the membrane diffusing capacity and Vc is the pulmonary capillary blood volume.

CARBOXYHEMOGLOBIN. Heavy smokers may have as much as 10% to 12% carboxyhemoglobin in their blood, and therefore the back-pressure of carbon monoxide in mixed venous blood entering the pulmonary capillaries cannot be assumed to be zero in such individuals. The steady-state method is more sensitive to errors caused by this problem than the single-breath technique. Carbon monoxide back-pressure may be estimated, and DL_{CO} calculations may be corrected for back-pressure of carbon monoxide using the Haldane equation.^{136,137} Alternatively, carboxyhemoglobin may be measured directly.¹³⁸ In either case, the measured DL_{CO} is adjusted, and both the unadjusted and the adjusted values are reported. DL_{CO} measurements should not be performed on patients who have been breathing oxygen-enriched mixtures immediately before the test; at least 20 minutes of breathing room air should be allowed before measurement of DL_{CO} .

Graham and associates demonstrated that carbon monoxide back-pressure has a more complex effect than suggested in the ATS standardization statement. To adjust properly for the effect of carbon monoxide on the diffusing capacity, not only must the direct effect of carbon monoxide back-pressure build-up be corrected, but also the indirect anemia effect of increasing carboxyhemoglobin.¹³⁹ The original ATS statement on this issue should be updated to account for both necessary adjustments.

ALTITUDE. As altitude increases and fractional concentration of inspired oxygen (FI_{O_2}) remains constant, pressure of inspired oxygen (PI_{O_2}) decreases and DL_{CO} increases approximately 0.35% for every 1 mm Hg decrease in alveolar PO_2 :

$$\text{Altitude-adjusted } DL_{CO} = \text{measured } DL_{CO} \times [1.0 + 0.0035(PA_{O_2} - 120)] \quad (24)$$

If alveolar PO_2 is not available, adjustments may be made for interpretative purposes, assuming a mean PI_{O_2} of 150 mm Hg at sea level:

$$\text{Altitude-adjusted } DL_{CO} = \text{measured } DL_{CO} \times [1.0 + 0.0031(PI_{O_2} - 150)] \quad (25)$$

assuming $PI_{O_2} = 0.21(P_{bar} - 47)$.

Normal Values for Pulmonary Diffusing Capacity

BODY SIZE. Body size is one of the factors that probably affect normal values⁶; diffusing capacity has been found to vary with body surface area (BSA, in square meters) according to the following equation, derived by Ogilvie and colleagues¹¹⁹:

$$DL_{CO} = 18.85 BSA - 6.8 \quad (26)$$

A better prediction¹⁴⁰ is based on height (H, in centimeters) and age (A, in years):

$$\text{Males: } DL_{CO} = 0.416(H) - 0.219(A) - 26.34 \quad (27)$$

$$\text{Females: } DL_{CO} = 0.256(H) - 0.144(A) - 8.36 \quad (28)$$

Values for DL_{CO} measured by analyzing the gases with a chromatograph are approximately 6% higher than values obtained with infrared meters.¹⁴¹

AGE. Maximal DL_{O_2} (i.e., DL_{O_2} during maximal exercise) has been found to decrease with increasing age according to the following equation:

$$\text{Maximal } DL_{O_2} = 0.67(H) - 0.55(A) - 40.9 \quad (29)$$

Age also affects DL_{CO} at rest (see previous discussion).

LUNG VOLUME. Diffusing capacity determined by the single-breath technique measured between FRC and TLC is relatively independent of lung volume in the same individual, although the diffusing capacity varies with lung volume among individuals, reflecting differences in alveolar-capillary surface with lung volume.⁴⁸

$$DL_{CO} = 13.67 + 4.36 \text{ BTPS}(TLC) - 0.2(A) \quad (30)$$

EXERCISE. Exercise raises DL_{CO} and DL_{O_2} by enlarging the surface area of functioning alveoli in contact with pulmonary capillaries (eFig. 25-10). This is due primarily to recruitment of capillaries. Exercise causes an approximate doubling of pulmonary diffusing capacity and pulmonary capillary blood volume.^{142,143} Huang and coworkers¹⁰⁹ studied 105 healthy subjects with the intrabreath method and reported reference equations for diffusing capacity at rest and during exercise based on age, sex, and height. Hsia and associates¹⁴³ found that DL_{CO} increased normally as cardiac output increased during exercise in patients who had undergone pneumonectomy compared with normal subjects. Although an upper limit to DL_{CO} with respect to oxygen uptake during exercise was observed by Stokes and colleagues,¹⁴⁴ using the intrabreath carbon monoxide method, our group and Hsia et al found no upper limit to DL_{CO} in normal subjects or in pneumonectomy patients with respect to cardiac output during exercise.^{116,145} Maximal values attained during exercise in patients who had undergone pneumonectomy were less than those attained by normal controls, as might be expected because the patients had been chronic smokers and probably had emphysema in the remaining lung.

As reviewed by Ceretelli and DiPrampo,¹⁴⁶ whether DL_{CO} reaches a true plateau during exercise appears to depend on the method used and the level of exercise attained by the subjects. Kinker and associates¹⁴⁷ used a modified steady-state method to determine breath-by-breath DL_{CO} during exercise. They found that the rise of DL_{CO} with increasing work was attenuated at high levels of exercise (maximal oxygen uptake, or $\dot{V}O_{2\max}$, approximately 4 L/min) in most subjects, suggesting that alveolar-capillary surface area tends to approach a maximum.¹⁴⁷ These findings are consistent with studies of capillary perfusion patterns in single alveolar walls visualized through a transparent thoracic window implanted in anesthetized dogs.¹⁴⁸ Results of this study agreed with a computer model of capillary flow developed by West and associates.¹⁴⁹

BODY POSITION. DL_{CO} is 15% to 20% greater in the supine than in the sitting position and 10% to 15% greater in the

sitting than in the standing position, because of the effects of changes in posture on pulmonary capillary blood volume.

ALVEOLAR OXYGEN PRESSURE. Alveolar PO_2 affects DL_{CO} because of the former's effect on the carbon monoxide reaction with hemoglobin. For example, diffusing capacity values measured at alveolar PO_2 values of 40 and 600 mm Hg are approximately 45 and 18 mL/min per mm Hg, respectively (see Fig. 25-11). Changes in DL_{CO} caused by variations in alveolar PO_2 in the physiologic range are much smaller. In patients with severe hypoxia (arterial $PO_2 < 40$ mm Hg), increased pulmonary blood flow and dilation of the pulmonary capillaries may increase the DL_{CO} . Hypoxia may also increase DL_{CO} as a result of its effect on the reaction rate between carbon monoxide and hemoglobin.

Diffusion properties of nitric oxide are similar to those of carbon monoxide; however, its rate of reaction with red blood cells is much greater.¹⁵² DL_{NO} primarily reflects DM, whereas DL_{CO} depends on both DM and Vc.^{151,152} In combination with DL_{CO} , Vc and DM can be determined in a single maneuver, based on the equation for the serial connection of resistances.¹⁵³ Using the combined DL_{NO} – DL_{CO} method, patients with COPD,¹⁵⁴ pulmonary arterial hypertension,¹⁵⁵ and parenchymal lung diseases^{156,157} have been studied, as well as the effects of exercise.^{152,153,158} In addition, reference values have been published.¹⁵⁹ The clinical utility of the DL_{NO} – DL_{CO} method remains to be determined by studies of healthy subjects under various experimental conditions and by studies of diverse patients by various laboratories.

Figure 25-16 Theoretical model showing the effect of pulmonary arterial pressure (PPA) and pulmonary venous pressure (PPV) on pulmonary capillaries at different levels of the lungs. The magnitude of PPA or PPV is indicated by the height of the fluid columns. For simplicity, the pressure in alveoli (Palv) is assumed to be equal to atmospheric pressure. Single-breath carbon monoxide diffusing capacity (DL_{CO}) is given in arbitrary units indicating the relative contribution of various zones of the lung. **A**, In the control state, at the bottom of the lung, both PPA and PPV are greater than Palv, and both keep the capillaries open. In the middle zone, PPA is greater than Palv and PPV, so PPA holds capillaries open. (The exact anatomy of capillaries in the zone in which Palv is greater than PPV is unknown; in the diagram, the compressed segment at the end of the capillary is meant to suggest a “Starling resistor” effect.) In the upper zone, Palv is greater than PPA and PPV, and capillaries are “collapsed.” **B**, When arterial inflow is occluded to the lower zone (indicated by red solid sphere), PPV is greater than Palv, so the capillaries in this zone remain distended and DL_{CO} is unchanged. **C**, When arterial inflow to the middle zone is occluded, Palv is greater than PPV and capillaries in this area are collapsed, so there is a decrease in DL_{CO} . **D**, When arterial inflow to the upper zone is occluded, the capillaries are already collapsed, so there is no change in DL_{CO} . **E**, When arterial inflows to the lower and middle zones are occluded simultaneously, capillaries in the middle zone may collapse. However, if PPA increases, capillaries in the upper zone may become distended, and the net result may be no change in DL_{CO} . Under these circumstances, if PPV also increases (**F**), DL_{CO} may actually increase. (Modified from Nadel JA, Gold WM, Burgess JH: Early diagnosis of chronic pulmonary vascular obstruction: value of pulmonary function tests. *Am J Med* 44:16–25, 1968.)

In the middle zone of the lung, capillaries are distended by pulmonary arterial pressure only; they are not affected by pulmonary venous pressure. DL_{CO} would be decreased by pulmonary vascular obstruction alone; however, DL_{CO} would be normal if the obstruction led to an increase in pulmonary arterial pressure that then distended apical capillaries that were not perfused previously. In addition, the DL_{CO} would increase if the pulmonary venous pressure increased, as long as the pulmonary capillaries remained patent despite pulmonary artery occlusion in this zone.

In the upper zone at the lung apex, pulmonary capillaries may be nondistended because Palv exceeds both pulmonary arterial and venous pressures (assuming the lung is ever in this condition). In this situation, obstruction of pulmonary arteries would not affect DL_{CO} . Changes in Palv would affect the analysis of the test and thus might affect DL_{CO} .¹⁷¹ In conclusion, a decreased DL_{CO} may support the diagnosis of pulmonary vascular obstruction, but a normal DL_{CO} does not rule out this diagnosis.¹³⁵

Restrictive Ventilatory Defects

DL_{CO} is reduced in interstitial pulmonary fibrosis and correlates with anatomic findings in resected lung tissue or on high-resolution CT scans. Although DL_{CO} is reduced in

at least half of these patients, the test may be normal in at least one third more who have abnormal responses to exercise and have documented fibrosis by lung biopsy or CT scan.¹⁷² DL_{CO} is often decreased in patients with many other forms of pulmonary restriction. DL_{CO} (expressed as percentage of predicted normal) best reflects the extent of interstitial fibrosing alveolitis on chest CT scan associated with systemic sclerosis.¹⁷³ DL_{CO} (expressed as percentage of predicted normal) also correlates closely with arterial oxygen desaturation during exercise in these patients. DL_{CO} is usually decreased in patients with asbestos-induced pleural fibrosis, who have a restrictive ventilatory defect without evidence of associated parenchymal abnormalities as documented by chest radiograph, bronchoalveolar lavage, and high-resolution CT scan.¹⁷⁴ In interstitial pulmonary fibrosis, DL_{CO} may better define pulmonary gas exchange impairment than resting arterial PO_2 , exercise alveolar-arterial PO_2 ((A-a) PO_2) differences, or 6-minute walk test arterial oxygen saturation.^{175,176}

When the diffusing capacity is reduced in patients with interstitial lung diseases, it is usually decreased out of proportion to the lung volumes; thus the DL_{CO}/VA ratio is also decreased. However, this may not be the case in all patients with a restrictive defect. A patient with sarcoidosis, for

example, may present with a TLC 50% of predicted normal, associated with a DL_{CO} that is also 50% of predicted normal, in which case the DL_{CO}/VA ratio is normal. Following treatment with systemic corticosteroids, the lung volume may return to normal, but diffusion may not, in which case the DL_{CO} and DL_{CO}/VA ratio may both be 50% of the predicted normal. In such cases, it is thought that the granulomas and fibrosis cause lasting damage to the alveolar membranes and capillaries, even though the lung volumes return to normal levels. Therefore clinical interpretation of the DL_{CO} corrected for alveolar volume in patients with interstitial lung diseases is limited. It should not be assumed that a normal DL_{CO}/VA ratio indicates that the capillary beds are functioning normally.

Rejection of Transplanted Lungs

Lung transplantation provides special challenges for physiologic evaluation. DL_{CO} is reported to be decreased abnormally in most patients with single-lung, double-lung, or heart and lung transplants. Great emphasis has been placed on the importance of detection of bronchiolitis obliterans in these patients as a potentially reversible manifestation of rejection that is lethal if treated inadequately or too late.¹⁷⁷ Given the frequency of diffusion defects in patients with lung transplants, and given that rejection is mediated via the vascular bed, it is surprising that little emphasis has been placed on the potential value of serial evaluation of DL_{CO} to detect rejection early.^{178,179}

A major limitation to the use of simple lung function monitoring in single-lung transplant patients is the bias caused by the contribution of the native lung. Ikonen and associates used relative ventilation, perfusion, and ventilation-perfusion ratio of the transplanted lung, as determined with multidetector *xenon-133* (^{133}Xe) radiospirometry, to assess function of the graft specifically. Fractions of FEV₁, FVC, and single-breath DL_{CO} were also determined using corresponding radiospirometric parameters to calculate their distribution between the lungs. This approach may have potential for distinguishing between acute rejection and infection.¹⁷⁸

REGULATION OF VENTILATION

MEASUREMENTS OF REGULATION OF VENTILATION

Ventilatory regulation may be assessed by measuring the ventilator response to hypoxia or hypercapnia or by measuring the overall respiratory drive. The response to hypoxia and hypercapnia has been assessed using rebreathing methods, which are less time-consuming and tiring than classic steady-state methods. In one rebreathing method described by Severinghaus and associates,¹⁸⁰ rapid step changes in the patient's PO_2 while PCO_2 is stabilized offer the advantage of a brief stable period of hypoxia. Respiratory drive can be assessed by measuring the inspiratory occlusion pressure at 100 msec (0.1 second), which is thought to reflect the entire neural output of the respiratory center. It is not influenced by conscious muscle effort and is less influenced by abnormal mechanical properties of the respiratory system than is measurement of ventilation. Other

methods, including electromyographic measurements of the diaphragm, the measurement of isometric inspiratory loads, and the use of drugs that stimulate the carotid body, have not been used often enough to establish their clinical utility.¹⁸¹

CLINICAL APPLICATIONS

Carbon Dioxide Responses

In general there are three clinical conditions associated with abnormal carbon dioxide responses: decreased central chemoreceptor response to carbon dioxide, neuromuscular disease preventing a normal response to carbon dioxide, and abnormalities of the mechanical properties of the respiratory system.

Patients with decreased central chemoreceptor response to carbon dioxide may have varied defects. Decreased responsiveness may result from congenital abnormalities or may be acquired following trauma or inflammatory lesions in the central nervous system. Decreased responsiveness may also result from chronic carbon dioxide retention with associated increased bicarbonate levels and increased buffer capacity of blood and other tissue fluids.

Patients with neuromuscular disease have normal chemoreceptor responses from the ventilatory centers but an inadequate peripheral response. Thus patients with myasthenia gravis cannot respond because of the defective neuromuscular junction, and patients with poliomyelitis cannot respond because of damaged anterior horn cells. These patients have decreased inspiratory work and diminished maximal inspiratory force in response to inhaled carbon dioxide and can be diagnosed using tests of respiratory muscle strength.

Patients with chronic airflow obstruction, pulmonary restriction, or deformities of the chest wall have mechanical limitations to thoracic expansion in response to inhaled carbon dioxide. These patients have normal chemoreceptor responses from the ventilatory centers, a normal peripheral response, but a mechanical limitation that prevents the respiratory muscles from increasing ventilation normally. Thus the ventilatory response to inhaled carbon dioxide may be reduced, but the response reflected by diaphragmatic *electromyography* (EMG), the $P_{0.1}$, is appropriate for the carbon dioxide.

Hypoxic Responses

There are few clinical indications for evaluation of hypoxic responses. The response to alveolar hypoxia has been used in patients with carotid body denervation to test the degree of depressed sensitivity to oxygen. Patients born at high altitude and patients with cyanotic congenital heart disease may have diminished response to hypoxia. The degree of abnormality can be assessed by administration of low-oxygen mixtures to breathe, but this is largely a research procedure.

In patients with chronic carbon dioxide retention, it may be worthwhile to test hypoxic responses because ventilation may be driven primarily by hypoxia. This possibility can be assessed by measuring the level of ventilation when the patient breathes room air and again with oxygen. Whereas normal subjects show a small decrease in ventilation, some

The subject should be prepared for these tests according to the recommendations of the ATS Workshop on Assessment of Respiratory Control in Humans.¹⁸² To minimize distractions, the subject should be positioned so as to be screened from the meters, monitors, and manipulators; preferably, the subject's eyes should be closed during the test procedure.

The ventilatory responses to hypoxia and hypercapnia vary considerably even in normal individuals. To prevent extraneous influences from further increasing this variability, the following recommendations are made: (1) studies should be performed in the fasting state with the bladder empty, (2) the subject should be comfortable and should rest for at least 30 minutes before the test, (3) the room should be quiet, (4) body temperature should be determined, (5) tests may be performed in either the sitting or semisupine position, (6) consideration should be given to preliminary evidence suggesting that normal subjects may have greater hypoxic responses when using a nose clip and mouthpiece than when using a mask, and (7) tests should be performed in duplicate with at least 10 minutes of rest between tests.

Ventilatory responses to hypoxia and hypercapnia are potentially hazardous. The clinical condition of the patient should be considered when evaluating the potential hazardous effects of the test procedure, and the usual precautions for safety of the patient used in any stress test should be taken.

Breath-Holding Time

With nose clips in place, the subject exhales to RV, inhales to TLC, and holds his or her breath as long as comfortably possible. Analyses of expired gases can be made to estimate end-tidal carbon dioxide concentrations. Breath-holding time equals the average time in seconds from the end of inspiration to TLC until the first expiration. The test is repeated until the breath-holding times or end-tidal carbon dioxide concentrations are reproducible. The mean value for predicted breath-holding at TLC is 78 seconds.¹⁸³ In six normal subjects studied by Davidson and colleagues,¹⁸⁴ reproducibility of the test at TLC was 75 ± 3 seconds at sea level (mean \pm standard error [SE]); subjects were trained until the expired end-tidal carbon dioxide was reproducible within 2 mm Hg.

Hypercapnic Response

As suggested by Read,¹⁸⁵ a reservoir bag is filled with a volume equal to the subject's VC plus 1 L with a mixture containing 7% carbon dioxide and 93% oxygen. The subject breathes room air and exhales into the room. Expired flow and end-tidal carbon dioxide are recorded. After a period to establish a stable baseline, valves are turned so the subject breathes in and out of the reservoir bag. The test is continued until the subject stops because of dyspnea, until the end-tidal PCO_2 equals 9%, or until 4 minutes have elapsed.

The ventilation in liters per minute (BTPS), either breath-by-breath or averaged over 5 to 10 breaths, is plotted on the ordinate, and the mean end-tidal carbon dioxide (in mm Hg) is plotted on the abscissa for the same periods (eFig. 25-13). The slope change in \dot{V}_E ($\Delta\dot{V}_E/\text{change in end-tidal } \text{PCO}_2$) is determined for all of the periods, preferably by linear least-squares regression analysis, eliminating the first 30 seconds of rebreathing.

The variability among normal subjects is large.^{6,185} The hypercapnic response has been shown to correlate with weight, height, and VC.¹⁸⁶ In subjects studied on two occasions 15 minutes apart, the mean \pm SE of the slope of the first test was 2.60 ± 0.11 , and that of the second test was 2.46 ± 0.10 . The mean \pm SE of the intercept on the carbon dioxide axis was 32.42 ± 0.67 mm Hg for the first test and 31.17 ± 0.71 mm Hg for the second test. When 10 of the same subjects were retested as long as 2 years later, the differences in slopes from earlier values varied from 0.04 to 3.57 L/min per mm Hg, and the differences in intercepts on the abscissa varied from 0 to 7.6 mm Hg.

Hypoxic Response

Following the method of Rebuck and Campbell,¹⁸⁷ a reservoir bag is filled with a volume equal to the VC of the subject plus 1 L with a mixture containing approximately 7% carbon dioxide, 70% nitrogen, and the balance oxygen. The subject breathes from and exhales into the room. Values for expired volume, end-tidal PO_2 , end-tidal PCO_2 , and oxygen saturation are recorded. When the end-tidal PCO_2 values become stable, appropriate valves are then turned so the subject rebreathes from the bag. The subject then takes three deep breaths to facilitate mixing; after these three breaths, the carbon dioxide value is recorded. Carbon dioxide is maintained at this level by manually adjusting flow through the carbon dioxide absorber. Rebreathing is continued until end-tidal PO_2 decreases to 45 mm Hg, oxygen saturation decreases to 75%, or the subject becomes distressed. If ventilation increases too rapidly, addition of oxygen at a rate of 125 to 200 mL/min will slow the rate of change.

Ventilation, in liters per minute BTPS (breath-by-breath or averaged over 5 to 10 breaths), is plotted on the ordinate, and the mean oxygen saturation (percentage) on the abscissa for the same periods (eFig. 25-14). The slope ($\Delta\dot{V}_E/1\%$ desaturation) is calculated, preferably by linear least-squares regression analysis. These values are reported in terms of the mean end-tidal PCO_2 during the test.

The variability of the hypoxic response during eucapnia in normal subjects is large. The difference in slopes indicates that the hypoxic response is very sensitive to the level of end-tidal PCO_2 selected. According to Rebuck and Campbell,¹⁸⁷ repeated measurements in five subjects from day to day showed a variance within individuals of 0.76 and between individuals of 7.75.

Inspiratory Occlusion Pressure

When the patient is breathing room air or while the hypercapnic or hypoxic response is being tested, P_{mouth} at 100 msec (0.1 second), $P_{0.1}$, or the *maximum rate of inspiratory pressure change* ($[dP/dt]_{\text{max}}$), can be measured. Brief inspiratory occlusion should be performed randomly, always preceded by three or more tidal breaths.¹⁸⁸ Out of view of the subject, the operator uses a syringe during expiration to close a Starling resistor arranged in series with the inspiratory channel so the channel is occluded. The syringe is decompressed as soon as possible after the inspiratory attempt is initiated. Recorder speed should be 50 mm/sec during the subject's inspiratory attempt. Alternatively, P_{mouth} and its differential (the change in pressure) can be

measured in the 10 to 50 msec before the inspiratory valve opens. This approach takes advantage of the inherent resistance of the valve and can be measured at a slow recording speed for every breath without requiring use of a Starling resistor or other maneuvers by the operator.¹⁸⁹ $P_{0.1}$ should be measured every minute and at the same time after the inspiratory effort begins (e.g., 100 ± 10 msec).

The $P_{0.1}$ measured during single partially occluded breaths, or the average (dP/dt)max of several breaths, is determined directly from the recording and plotted on the ordinate. Mean \dot{V}_E calculated from three or more breaths preceding inspiratory occlusion, end-tidal PCO_2 , or arterial oxygen saturation is displayed on the abscissa (eFig. 25-15).

Kryger and colleagues¹⁹⁰ found a mean $P_{0.1}$ of 2.6 cm H_2O (range, 1.5 to 5.0 at an arterial PCO_2 of 39 to 42 mm Hg). Gelb and coworkers¹⁹¹ found a mean \pm SD increase of 0.52 ± 0.19 cm H_2O /mm Hg PCO_2 during increasing hypercapnia. Matthews and Howell¹⁸⁹ found (dP/dt)max to vary during quiet breathing from 12.5 to 25 cm H_2O /sec. During hypercapnia the increase in (dP/dt)max ranged from 0.6 to 4.6 cm H_2O /sec per mm Hg carbon dioxide, and end-tidal PCO_2 increased from 50 to 60 mm Hg. Whitelaw and associates¹⁸⁸ found a mean $P_{0.1} \pm$ SD of 13.2 ± 0.76 cm H_2O during constant hypercapnia (end-tidal PCO_2 of 56 mm Hg). Matthews and Howell¹⁸⁹ found that individual breath-to-breath (dP/dt)max varied up to 20%.

patients with chronic carbon dioxide retention show a marked decrease in ventilation. Although this decreased response is unusual in patients with chronic airflow obstruction who are treated with oxygen, it is important to be aware that such a response can be seen in some patients, who may require assisted ventilation.

VENTILATION-PERFUSION RELATIONSHIPS

For discussion of ventilation, blood flow, and gas exchange, see Chapter 4.

MEASUREMENTS OF VENTILATION-PERFUSION RELATIONSHIPS

Inhaled air and pulmonary capillary blood flow are not distributed uniformly or in proportion to each other, even in the normal lung. Distributions of ventilation and blood flow are altered by posture, lung volume, and exercise not only in healthy subjects but even more so in patients with respiratory disease. The most common cause of arterial hypoxemia is increased mismatching of ventilation and perfusion, resulting in regional hypoventilation relative to perfusion (eTable 25-1). Whereas samples of alveolar gas and pulmonary capillary blood cannot be obtained to analyze gas exchange, inspired and expired gas (gas entering and leaving the alveoli) and mixed venous (blood entering the pulmonary capillaries) and arterial blood can be obtained and analyzed.

CLINICAL APPLICATIONS

The various methods of measuring ventilation-perfusion relationships have been used widely in the diagnosis and management of patients with various pulmonary disorders. This is not surprising because almost every pulmonary disease affects the delicate match between ventilation and perfusion early in the process, with the matching becoming worse as the disease progresses.

Understanding ventilation-perfusion mismatching may be essential to proper diagnosis and management. For example, measurement of physiologic dead space has provided insights into the gas exchange defects of the patient in the intensive care unit and of the patient with chronic pulmonary embolism who presents with the complaint of exertional dyspnea. Measurement of intrapulmonary shunts by having a patient breathe pure oxygen can be used to estimate the size of shunts and assess efficacy of therapeutic embolization of shunt vessels.

Although the measurement of distribution of ventilation-perfusion ratios has taught us a great deal about the pathophysiology of ventilation-perfusion matching in pulmonary disease, it has not been useful as a clinical tool. On the other hand, radioisotope lung scans are critically important in the management of many of our patients, not only those with pulmonary vascular problems, but also patients who have undergone a single-lung transplant, in whom we can understand the role played by the native lung as well as the graft.

APPLICATIONS OF PULMONARY FUNCTION TESTS

SCREENING STUDIES

As suggested by Comroe and Nadel,²⁵² screening pulmonary function tests should separate subjects who have normal lungs from those who have abnormal lungs in a few minutes of the patients' time, with little or no discomfort. The apparatus should be inexpensive and portable and should require little or no technical training to operate. Tests should be free from error and should pinpoint the specific functional abnormality and its location in a quantitative manner.

The single test that best fits this definition is spirometry. Spirometry is generally able to separate those with normal lungs from those with abnormal lungs; it is inexpensive, can be portable, and requires less training. Screening tests always include spirometry, with the understanding that the major limitation of spirometry is the inability to measure total lung volume. Additional tests may be added for screening pulmonary function as the situation demands.

Screening tests are useful for early detection of pulmonary or cardiopulmonary disease (e.g., emphysema, pulmonary fibrosis, pulmonary vascular disease); differential diagnosis of patients with dyspnea; detection of the presence, location, and extent of regional disease; evaluation of patients before surgical procedures; determination of the risk of certain diagnostic procedures; early detection of respiratory failure and monitoring of treatment in critical care units; quantitative evaluation of specific treatment in patients with known pulmonary disease; periodic examination of pulmonary function in workers whose occupations are associated with known pulmonary hazards; and epidemiologic studies of populations to provide clues regarding the pathogenesis of pulmonary disease.

In obstructive ventilatory defects, screening pulmonary function tests permit the diagnosis in asymptomatic patients on the basis of decreased $FEF_{25\%-75\%}$ from spirometry and decreased maximal flow at low lung volumes from flow-volume curves. In more advanced obstruction, FEV_1 , FEV_1/FVC ratio, and maximal flows at all lung volumes may be abnormally decreased. The evidence of airway obstruction may be associated with uneven distribution of ventilation, as reflected by an abnormal single-breath nitrogen washout test, and associated hyperinflation, as reflected by increased RV and FRC. If the airway obstruction is severe (FEV_1/FVC ratio < 0.4), the TLC measured by single-breath dilution may be underestimated significantly.^{43,44}

In restrictive ventilatory defects, if airway function is normal, screening pulmonary function tests permit an early diagnosis by the finding of an increased FEV_1/FVC ratio associated with increased maximal expiratory airflow. With more advanced disease, TLC, VC, and associated lung volumes are decreased, with evidence of uneven distribution of ventilation. In mixed ventilatory defects, the interpretation of the spirogram may be aided by examining FEV_1 as a percentage of predicted normal rather than as a percentage of FVC; however, mixed defects are more easily defined by measurement of TLC using a multiple-breath dilution technique or, preferably, body plethysmography.

eTable 25-1 Causes of Hypoxemia: The Effect on Alveolar-Arterial PO_2 Differences and Arterial PCO_2

Cause	Effect on Alveolar PO_2	Effect on (A-a) PO_2	Effect on Arterial PCO_2
Normal lungs/inadequate oxygenation			
Deficiency of oxygen in atmosphere	↓	↔	↓
Hypoventilation (neuromuscular disorder)	↓	↔	↑
Pulmonary disease			
Hypoventilation (airway/parenchymal disorder)	↓	↔	↑
Diffusion abnormality	↓* [†]	↑* [†]	↓
Ventilation-perfusion imbalance	↓ [†]	↑ [†]	↓ ↔, or ↑
Right-to-left shunts	↓	↑	↓, ↔, or ↑
Inadequate transport/delivery of oxygen			
Anemia	↔	↔	↔
General/localized circulatory insufficiency	↔		↔
Inadequate tissue oxygenation			
Abnormal tissue demand/poisoned enzymes/edema	↔	↔	↔

*Infrequently observed at rest but more likely during exercise.

[†]Unless patient is hyperventilating.

↑, increased; ↔, no change; ↓, decreased.

Resting Ventilation

Minute ventilation under resting conditions is defined as the amount of air exhaled per minute (\dot{V}_E). It can be measured readily using a recording spirometer equipped with a carbon dioxide absorber. (The measured expired volume must be corrected for the amount of absorbed carbon dioxide.) Many laboratories use a mouthpiece equipped with valves that separate inhaled and exhaled gases, permitting collection of exhaled air in a plastic bag or meteorologic balloon in preference to the use of a spirometer. Most commercial devices now direct expired gas through a pneumotachygraph and use a computer to integrate the flow signal to calculate expired volume. The volume of exhaled gas collected is then measured with a 120-L (Tissot) spirometer or with a dry-gas meter. For use at the bedside, a Wright spirometer¹⁹² is preferred; it is used commonly in surgical recovery rooms and critical care units. From \dot{V}_E , it is possible to estimate alveolar ventilation (see discussion later), using an assumed value for *dead space* (V_D):

$$V_D (\text{mL}) = \text{subject's body weight (lb)} \quad (32)$$

Measurement of resting \dot{V}_E usually plays a minor role in routine assessment of pulmonary function, because patients with advanced disease of the lungs often breathe with a normal tidal volume and respiratory frequency. The attending physician may wish to obtain an accurate record of resting \dot{V}_E if hypoventilation or an abnormal respiratory pattern is suspected, such as that associated with central nervous system lesions or psychogenic disorders. Resting \dot{V}_E in normal subjects has been studied in detail: men breathe at an average rate of 16 breaths/min, women breathe at 19 breaths/min with much individual variation, and sighs happen at an average of 9 per hour in men and 10 per hour in women.¹⁹³

Because the attempts to measure \dot{V}_E change an automatic, unconscious process to one of concern to the subject, it is difficult to obtain accurate measurements of the rate and pattern of resting ventilation. In addition to making measurements when the subject is unaware, investigators have used magnetometers attached to the chest wall and impedance plethysmography¹⁹⁴ to measure ventilation and the pattern of breathing accurately.

Measurement of resting \dot{V}_E plays an important, but previously neglected, part in management of patients in danger of developing respiratory failure from hypoventilation (e.g., patients with obesity and sleep disorder syndromes). In such patients, and in patients in postoperative states, with drug intoxication, or with neuromuscular disease, measurement of \dot{V}_E is as important as measurement of the usual vital signs (heart rate and blood pressure) and should be obtained at frequent intervals.

The Bohr Equation for Respiratory Dead Space

The Bohr equation, applied to a particular gas X, is as follows. Expired gas is the total volume of gas leaving the nose and mouth between the beginning and the end of a single exhalation (V_E). V_A indicates the volume of alveolar gas contributed to the exhaled gas and does *not* refer to the total volume of gas in the alveoli. The amount of gas X in V_E , V_A , or V_D is the product of its fractional concentration

(F_X) and the volume in which gas X is contained. Therefore,

$$F_{E_X} V_E = F_{A_X} V_A + F_{D_X} V_D \quad (33)$$

If the gas in question is carbon dioxide, this equation is simplified, because inspired air contains practically no carbon dioxide ($F_{ACO_2} = 0.0005$), and the Bohr equation becomes

$$V_D = \frac{[F_{ACO_2} - F_{ECO_2}]}{F_{ACO_2}} V_E \quad (34)$$

“Physiologic” Dead Space (also called Wasted Ventilation)

In the Bohr equation for respiratory dead space, F_{ECO_2} and V_E can be measured easily, but F_{ACO_2} is difficult to obtain, and V_D cannot be calculated unless the correct value for F_{ACO_2} is known. Because there is almost always complete equilibrium between alveolar PCO_2 and end-pulmonary capillary PCO_2 , arterial PCO_2 represents a mean alveolar PCO_2 over several respiratory cycles, provided that arterial blood is sampled over this same period and the patient does not have a significant venous-to-arterial shunt. Thus arterial PCO_2 can replace alveolar PCO_2 , and the Bohr equation becomes

$$V_D = \frac{[P_{aCO_2} - P_{ECO_2}]}{P_{aCO_2}} V_E \quad (35)$$

In the ideal case, anatomic and “physiologic” dead spaces are equal. However, in patients with uneven ventilation–blood flow ratios in the lung, the physiologic dead space is larger than the anatomic dead space, because regions with decreased blood flow in relation to ventilation act as regions of wasted ventilation or respiratory dead space.¹⁹⁵

By substituting arterial PCO_2 for alveolar PCO_2 in the Bohr equation, it is possible to calculate physiologic dead space. This includes anatomic dead space and alveolar dead-space ventilation. The latter includes ventilation of alveoli without perfusion; alveoli with decreased perfusion and increased, normal, or slightly decreased ventilation; and alveoli with normal perfusion and marked overventilation. Because it is technically impossible to distinguish the various types of increased \dot{V}_A/Q_C ratios, we assume that part of alveolar ventilation to regions with diminished perfusion goes to regions without any blood flow. That is, the physiologist assumes two compartments: one with and one without perfusion. Overventilation relative to perfusion wastes ventilation with respect to oxygen transfer because of the shape of the oxygen-hemoglobin dissociation curve. Little oxygen is added to blood by increasing alveolar PO_2 from 100 to 140 mm Hg. This excess ventilation is not wasted with respect to carbon dioxide elimination, because increased ventilation decreases arterial carbon dioxide. Regions with excess ventilation are usually accompanied by other regions with diminished ventilation and increased PCO_2 . Ventilation is still “wasted” with respect to carbon dioxide, because it is not distributed proportionately to perfusion. Assessment of wasted ventilation is essential for the proper management of critically ill patients in the intensive care unit and for the diagnosis of patients with pulmonary vascular obstruction in the pulmonary exercise laboratory.

Alveolar Air Equation

The measurement of alveolar PO_2 and PCO_2 from analysis of a single sample of exhaled alveolar gas is subject to considerable error, but mean alveolar PO_2 can be calculated accurately. The underlying principle is based on the concept that at sea level the total pressure of gases (oxygen, carbon dioxide, nitrogen, and water) in the alveoli equals 760 mm Hg, and that if the partial pressures of any three of these four are known, the fourth can be obtained by subtraction. As derived in Chapter 4,

$$760 \text{ mm Hg} = PO_2 + PCO_2 + PN_2 + PH_2O \quad (36)$$

In general, water vapor pressure at 37°C is approximately 47 mm Hg, and this presents no problem. Arterial PCO_2 is used to represent mean alveolar PCO_2 , because arterial blood coming from all the alveoli approaches an integrated value of alveolar PCO_2 with respect to different regions of the lung and to different times during the respiratory cycle. It is also assumed that $PN_2 = 563$ mm Hg. This would be true if the *respiratory gas exchange ratio* (R) were 1 (i.e., the amount of carbon dioxide added to the alveoli equals the amount of oxygen removed from the alveoli per minute). Actually, the amount of oxygen removed per minute is greater than the amount of carbon dioxide added:

$$R = \frac{200 \text{ mL } CO_2/\text{min}}{250 \text{ mL } O_2/\text{min}} \cong 0.8 \quad (37)$$

With an R of 0.8, the nitrogen molecules are slightly more concentrated, because the same number of nitrogen molecules is present in a smaller volume. If the alveolar nitrogen concentration increases to 81%, alveolar PN_2 increases to 577 mm Hg and alveolar PO_2 falls to 96 mm Hg. It is therefore essential to measure R to calculate alveolar PN_2 accurately. The precise formula (assuming inspired PCO_2 is zero) is

$$PAO_2 \cong \left(\begin{matrix} \text{(unknown)} \\ \text{(known)} \end{matrix} \right) (PIO_2 - PACO_2) \times \left(\begin{matrix} \text{(measured)} \\ \text{(correcting factor)} \end{matrix} \right) \left(FIO_2 + 1 - \frac{FIO_2}{R} \right) \quad (38)$$

where PIO_2 (moist) at sea level is calculated as 20.93% of $(760 - 47) = 149$ mm Hg, and alveolar carbon dioxide pressure ($PACO_2$) is assumed to be equal to the arterial PCO_2 , which can be measured accurately.

The *alveolar air equation* is often approximated to estimate alveolar-arterial oxygen differences for clinical purposes (assuming $PACO_2 = PaCO_2$):

$$PAO_2 = PIO_2 - \frac{PaCO_2}{R} \quad (39)$$

The *alveolar-arterial PO_2 difference* ($(A-a)PO_2$) has been shown to be larger in older subjects than in younger ones.¹⁹⁶ According to Mellemaard,¹⁹⁷ the regression with age is expressed as $(A-a)PO_2 = 2.5 + 0.21 \times \text{age (in years)}$. Mellemaard's study was performed on 80 healthy, seated subjects whose ages ranged from 15 to 75 years.

Calculation of Alveolar Ventilation

Carbon dioxide in exhaled gas must all come from alveolar gas. As derived in Chapter 4, this equation is as follows:

$$\dot{V}_A(\text{mL}) = \frac{\dot{V}_{CO_2}(\text{mL}) \times 863}{PACO_2} \quad (40)$$

Relation of Alveolar Ventilation to Pulmonary Blood Flow

Equation 41, derived in Chapter 4, relates the factors that determine the adequacy of alveolar ventilation:

$$\frac{\dot{V}_A}{\dot{Q}_C} = \frac{863(C\bar{V}CO_2 - Cc'CO_2)}{PACO_2} \quad (41)$$

where \dot{Q}_C is pulmonary capillary blood flow, $C\bar{V}CO_2$ is the carbon dioxide concentration in mixed venous blood, $Cc'CO_2$ is the carbon dioxide concentration in the end-pulmonary capillary blood, \dot{V}_A is alveolar ventilation, $PACO_2$ is alveolar carbon dioxide tension, and 863 is a constant to correct for changes from alveolar fraction to alveolar pressure of carbon dioxide. In any individual the mixed venous blood distributed to all pulmonary capillaries has the same carbon dioxide concentration, and end-pulmonary capillary blood has the same PCO_2 as alveolar gas; therefore alveolar PCO_2 is determined by the ratio \dot{V}_A/\dot{Q}_C .

Calculation of Quantity of Venous-to-Arterial Shunt

For a more detailed discussion of pulmonary shunts, see Chapter 61 which discusses pulmonary arteriovenous malformations and other pulmonary vascular abnormalities.

When a patient has a venous-to-arterial shunt, arterial blood contains some mixed venous blood that has bypassed the lungs and some well-oxygenated blood that has passed through the pulmonary capillaries. The equation that expresses this relationship for blood is analogous to the Bohr equation for calculation of respiratory dead space:

$$\dot{Q}_S = \frac{Cc'O_2 - CaO_2}{Cc'O_2 - C\bar{V}O_2} \times \dot{Q} \quad (42)$$

where \dot{Q}_S is shunt blood flow, $Cc'O_2$ is the oxygen content of end-capillary blood, CaO_2 is the oxygen content of arterial blood, $C\bar{V}O_2$ is the oxygen content of mixed venous blood, and \dot{Q} is total blood flow.

Arterial and mixed venous blood can be obtained, so the arterial concentration of oxygen and $C\bar{V}O_2$ can be measured. The quantity of blood flowing through the shunt can be determined by having the patient breathe pure oxygen for a sufficient time to wash all of the nitrogen from the alveoli. Alveolar PO_2 is then equal to 760 – alveolar PH_2O – alveolar PCO_2 , or approximately 673 mm Hg. Under these conditions, there is no alveolar-to-end-capillary difference, and end-capillary blood can be assumed to contain an amount equal to the oxygen capacity of hemoglobin plus 2.0 mL of dissolved oxygen per 100 mL.

“Venous admixture” or “physiologic shunt” can be estimated by the method of Lilienthal and associates.¹⁹⁸ “Shunt” means decreased \dot{V}_A/\dot{Q}_C ratios and includes perfused alveoli without ventilation; very poorly ventilated alveoli with normal, increased, or slightly decreased perfusion; and ventilated alveoli with markedly increased perfusion. In this situation, the physiologist assumes two compartments: one with and one without a complete shunt.¹⁹⁹

If a patient is given pure oxygen to breathe, it is possible to distinguish a right-to-left shunt from a ventilation-perfusion abnormality. Alveolar and arterial PO_2 values expected in an ideal lung, with \dot{V}_A/\dot{Q}_C ratio imbalance, and with right-to-left shunt are given in eTable 25-1.

Pure oxygen replaces nitrogen with oxygen in all gas-exchange units that have patent airways, even in the presence of severe airway obstruction or pulmonary restriction; this leaves only oxygen, carbon dioxide, and water in the air spaces. Under these conditions,

$$PAO_2 = PA_{TOTAL} - PACO_2 - PAH_2O \quad (43)$$

Total pressure (PA_{TOTAL}) and water vapor pressure (PAH_2O) are the same in all patent gas-exchange units; thus alveolar PO_2 differences between units exist only when there are differences in PCO_2 . In ideal lungs or lungs with a \dot{V}_A/\dot{Q}_C imbalance, the high alveolar PO_2 corrects the ventilation-perfusion imbalance; arterial PO_2 values are also high, provided all nitrogen is washed out of communicating units by oxygen.

In most normal subjects, the right-to-left shunts are distal to the gas-exchange units (so-called postpulmonary shunts). These shunt vessels include bronchial veins, mediastinal-to-pulmonary veins, and thebesian vessels (left ventricular muscle to left ventricular cavity). In some patients, intracardiac shunts, pulmonary arteriovenous malformations, or perfusion of nonventilated alveoli produce pulmonary shunts. Most shunts in patients with pulmonary disorders involve perfusion of nonventilated alveoli. For clinical purposes the amount of right-to-left shunt may be estimated from the fall in arterial PO_2 below the expected value of 673 mm Hg, as long as the PO_2 is sufficient to saturate hemoglobin (i.e., more than 200 mm Hg). For every 2% shunt, PO_2 decreases 35 mm Hg.

Measurement of Ventilation-Perfusion Relationships Using Insoluble Gases

For a more detailed discussion of ventilation-perfusion relationships, see Chapter 4.

^{133}Xe is a relatively insoluble gas with a blood-gas partition coefficient of approximately 0.13.²⁰⁰ When it is inhaled, ^{133}Xe can be used to measure regional ventilation per unit lung volume, and when it is dissolved in saline and injected intravenously, it can be used to measure regional blood flow.²⁰¹ When either of these procedures is followed by rebreathing in a closed circuit, a plateau is obtained that reflects the product of lung volume detected by the counter and the geometric factor for ^{133}Xe ; for this purpose, the subject is switched into a closed circuit at the end of the injection. Measurements that can be obtained are illustrated in eFigure 25-16. Following intravenous injection, peak activity reflects the appearance of the isotope distributed in proportion to pulmonary blood flow; because of its low blood-gas partition coefficient, about 85% of the isotope passes into the alveolar gas, where it remains as long as the subject holds his or her breath. On resumption of breathing, the distribution reflects ventilation of perfused tissue. A slow clearance implies units with a relatively low \dot{V}_A/\dot{Q}_C ratio. Because of the overlap of many units (at least 10^7) with a single counting field, a functional definition of the \dot{V}_A/\dot{Q}_C ratio in this manner is more closely related to pulmonary gas exchange than a ratio obtained by dividing a measurement of regional ventilation by a separate measurement of regional perfusion.

The lower graph of eFigure 25-16 shows a wash-in of ^{133}Xe in a closed circuit followed by a washout. The equi-

libration plateau is evidence that the isotope concentration is the same in all alveoli. Local count rates then reflect the volume of alveolar gas in the counting fields. Perfusion per unit volume is obtained by dividing the peak counts for any region by the counts at equilibrium after intravenous injection. Both measurements should be made at the same lung volume, so geometric factors in the chest wall and differences in detector sensitivity do not influence the results.

If several VC breaths are taken at the beginning of the test, healthy subjects reach equilibration after rebreathing for 1 to 2 minutes or less. Patients with airway obstruction may not reach full equilibration in 20 minutes because isotope is accumulated in the blood and chest wall; rebreathing may then be terminated at 4 minutes. Ventilation per unit of lung volume may be obtained from the initial slope or half-time of the wash-in or washout of ^{133}Xe (see eFig. 25-16). Beyond the half-time, the washout curve cannot be interpreted because of activity in the chest wall and in the recirculating blood. Ventilation per unit of lung volume may also be obtained from the activity during a breath held subsequent to taking in a tidal volume of ^{133}Xe ; activity is divided by the plateau level at the same lung volume.

Alternatively, a bolus of ^{133}Xe may be injected close to the mouthpiece just before the start of inhalation, which is then continued until full inhalation. Under these circumstances the bolus is distributed in a pattern reflecting the early phase of inspiration starting at end-expiration. Because ventilation tends to be sequential, it is preferable to label the whole tidal breath. A bolus given at the beginning of inspiration after a maximal exhalation to RV is distributed preferentially to the lung apex. An inspiratory capacity breath of ^{133}Xe reflects regional compliance, not regional ventilation, and measures the regional inspiratory capacity. Thus it is possible to use the gas dilution principle to calculate regional inspiratory capacity or regional VC using a variety of radioisotopes.²⁰²

The most widely used radioisotope study of the lung is the perfusion scan following intravenous injection of human serum albumin microspheres or microaggregates labeled with technetium-99m (^{99m}Tc).²⁰³ Particles are 20 to 50 μm in diameter and impact in small pulmonary vessels in proportion to local perfusion. Regional perfusion is measured, not perfusion per unit volume, so the volume of lung in the counting field influences the measurement. Calculations suggest that from 1 mg of protein, particles of 500, 100, and 30 μm in diameter obstruct, respectively, 0.12%, 0.31%, and 0.26% of the vascular bed.²⁰⁴ On this basis, injection is potentially hazardous in patients with severe pulmonary vascular disease, and deaths in this situation have been recorded. However, with reasonable precautions, the risk is minimal. Passage of particles into the systemic circulation through right-to-left intrapulmonary or intracardiac shunts does not appear to be accompanied by side effects. The radiation dose from most pulmonary isotopic procedures is low and confined primarily to the lungs. A typical ^{133}Xe or ^{99m}Tc study yields 0.2 to 0.4 rad (the annual permitted dose is 5 rad).

Distribution of Ventilation-Perfusion Ratios

Distribution of perfusion in relation to ventilation of the lung may be analyzed on the basis of a region or lobe or for the lung as a whole and expressed in terms of physiologic

shunt, physiologic dead space, and other compartments or in terms of ventilation-perfusion ratios. In an approach developed by Wagner and colleagues,²⁰⁵ the lung is assumed to consist of a large number of homogeneous compartments in parallel, each with its own ventilation, blood flow, and appropriate gas concentrations. Distribution of ventilation-perfusion ratios is evaluated with six inert gases of varying solubility dissolved in saline and infused intravenously and concurrently at a constant rate. Under these circumstances in the steady state, the amount of any gas exchanging between alveoli and pulmonary capillary blood is identical to that exchanging between alveoli and atmosphere. For each compartment, the quantity of gas is a function of the ventilation-perfusion ratio and the blood-gas partition coefficient for the gas in question, expressed as a fraction of that in the mixed venous blood. For the lung as a whole, the mixed arterial concentration is a blood flow-weighted mean of the values for several compartments, and the mean expired level is similarly a ventilation-weighted mean of the compartmental values. These parameters are measured directly, together with the cardiac output and the minute volume of ventilation. They are used to calculate the corresponding mixed venous and alveolar concentrations and then a distribution of ventilation-perfusion ratios that is compatible with the arterial and alveolar concentrations of all gases concurrently (eFigs. 25-17 and 25-18).

The limitations of the method include the limited accuracy of current chromatographic techniques for gas analysis. In addition, it does not provide a unique solution, because the same arterial and alveolar gas concentrations could result from other distributions of ventilation and perfusion in the lung. Wagner and associates²⁰⁶ also reported a modification of the multiple inert gas method that permits estimation of the levels of inert gases in peripheral venous blood, rather than arterial blood, which may prove to be of considerable clinical interest.

ARTERIAL BLOOD GASES

MEASUREMENTS OF ARTERIAL BLOOD GASES

The physiologic determinants of arterial oxygen levels and acid-base balance are reviewed in detail in Chapter 4 and Chapter 7, respectively.

Invasive Measurements

pH. The pH of blood is now measured almost entirely by the use of the pH electrode (eFig. 25-19). This device takes advantage of the discovery that an electrical potential difference exists across some types of glass membranes placed between solutions of different pH. By maintaining one side of the membrane at a known pH with a buffer solution (pH = 6.84), the pH of the solution placed on the other side of the membrane can be calculated from the potential difference generated, using the Nernst equation. The modern pH electrode is made up of two cells. The measurement half-cell consists of a fine capillary tube of pH-sensitive glass separating the introduced sample (as little as 25 μ L) from the buffered solution, and a silver/silver chloride electrode to conduct the generated potential difference to the

electronic circuitry. The reference half-cell usually contains a calomel (mercury/mercurous chloride) electrode in an electrolyte solution to provide a constant reference voltage and is connected to the measurement half-cell by a contact bridge to complete the circuit. These two cells are enclosed together in a sealed jacket and are maintained at a constant temperature (see eFig. 25-19).

The potential difference generated across the glass membrane is a linear function of the pH. Thus it is usually adequate to calibrate the electrode with two buffered solutions of known pH that span a significant portion of the range expected in the samples to be measured. The normal range for arterial pH at sea level is 7.35 to 7.45 units. Even preliminary deviations from this range can be interpreted only by also examining the PCO₂, making use of the Henderson-Hasselbalch equation,

$$\text{pH} = 6.10 + \frac{\log(\text{HCO}_3^-)}{0.03 \times \text{PCO}_2} \quad (44)$$

to infer whether the deviation in pH is due primarily to a metabolic or a respiratory cause and whether it is due to an acute or chronic disturbance. In clinical use the pH meter has proved to be a rugged, dependable device. Repeated measurements of a single sample by the same instrument fall within a narrow range of ± 0.02 unit (± 2 SD). Generally there is good agreement among the values obtained on unknown samples by the different instruments used by laboratories enrolled in quality-control programs (SD = 0.014 pH unit has been obtained in more than 800 laboratories).²⁰⁷ This remarkable accuracy depends on the integrity of the differential permeability of the glass membrane to hydrogen ions. The permeability may be altered by the deposition of protein or by the development of cracks on the membrane surface. Proper quality control requires that pH calibration be checked at one point before each series of pH determinations and at two major points every 4 hours. A number of standard phosphate buffer solutions are suitable for routine calibrations and are available commercially. Protein contamination of the membrane can be minimized by flushing the electrode with a cleaning solution at regular intervals (every 10 samples) and by taking care to follow injections of blood with injections of saline (not distilled water).

Carbon Dioxide. Early chemical methods for measuring gas concentrations in blood were laborious and demanding. They involved liberating chemically bound oxygen and carbon dioxide in blood by adding chemical agents to a sample kept in a closed vessel. The quantity of gas released was then measured by a manometric²⁰⁸ or volumetric²⁰⁹ method. Carbon dioxide was then selectively absorbed, and the change in volume permitted calculation of the content of the blood sample of the two gases. These tedious and technically demanding methods gave accurate values for the content of the two gases in blood. Determination of pressure required measurement of the content of the gases in plasma alone, after separating plasma from red blood cells in a closed system. Alternatively, back-calculation of pressure could be made by measurement of blood hemoglobin content combined with measurements and calculations of the quantities of the gases transported in the cells and proteins of blood.

The breakthrough in the measurement of carbon dioxide came with the development of the membrane-covered carbon dioxide electrode (eFig. 25-20). This device exploits the principles of the pH electrode and the known relationship between PCO_2 and pH in a buffered solution. The sample to be analyzed is separated from a buffer solution by a membrane permeable to carbon dioxide. The carbon dioxide molecules that diffuse through the membrane alter the concentration of carbonic acid and therefore the concentration of hydrogen ion in the buffered solution:

A pH meter reads the resulting change in pH with the output scaled in terms of PCO_2 . The time for response of the carbon dioxide electrode depends on the concentration and volume of the buffered solution, the diffusion properties of the artificial membrane, and the thickness of a second “stabilizing membrane” placed over the pH-sensitive glass. With silicone-rubber membranes, the 95% response time has been reduced to as little as 10 seconds (see eFig. 25-20).

Perhaps because it incorporates a pH electrode in its design, the PCO_2 electrode also has the advantages of precision and dependability if calibrated regularly. As with the pH electrode, a one-point calibration should be checked before each series of blood-gas measurements, and two-point calibrations every 4 to 8 hours or whenever the one-point calibration indicates the need for readjustment of more than 2 mm Hg PCO_2 . The range of repeated measurements of samples of blood equilibrated under controlled conditions to PCO_2 of 20 to 60 mm Hg is ± 3.0 mm Hg, and tests with commercially available, sealed buffer solutions with different PCO_2 values show similar reproducibility with a variety of blood-gas measuring devices. The agreement among devices of laboratories enrolled in quality-control programs is also good.

The normal range of values for PCO_2 varies with altitude. At sea level, it ranges from 36 to 44 mm Hg.²¹⁰ In Salt Lake City, Utah (elevation 1340 to 1520 m), the range is reported to be 30 to 40 mm Hg.²¹¹

Oxygen

OXYGEN PRESSURE. As with the measurement of PCO_2 , the development of an accurate, stable electrode has almost entirely supplanted the use of older chemical methods for measuring total blood oxygen content and then back-calculating PO_2 . The principle of the oxygen electrode differs from that of the pH and PCO_2 electrodes in that the oxygen electrode measures a current generated by the presence of the relevant molecule, rather than a potential difference. The device consists of platinum and silver electrodes placed in potassium chloride solutions, a polarizing voltage of 0.5 to 0.6 volt, and an electrolyte bridge to complete the circuit. Oxidation takes place at the silver electrode, where silver reacts with chloride ions to form silver chloride. This reaction produces electrons, which are consumed by the reduction of oxygen at the platinum electrode. The flow of electrons (current) is thus proportional to the concentration of oxygen at the platinum electrode (eFig. 25-21).

Clark²¹² developed a useful electrode based on this principle. The important features of the Clark electrode are that it minimizes oxygen consumption by the use of a thin platinum electrode and ensures a constant diffusion distance

between the surface of the electrode and the sample by covering the electrode with an oxygen-permeable membrane. The surface area of the platinum electrode and the permeability of the membrane to oxygen determine the sensitivity and response time of the electrode. However, the larger the electrode and the more permeable the membrane, the more rapidly oxygen is consumed, causing PO_2 to fall in small samples as the measurement is made. For most available devices, the compromises made result in a 95% response time of about 50 seconds.

A peculiarity of the oxygen electrode is that slightly different currents are generated when gases and liquids at the same PO_2 are introduced. The magnitude of the difference is usually 3% to 4%, depending on the electrode diameter, the nature and thickness of the membrane, and the flow of the sample around the electrode. A correction factor is sometimes introduced into the calculation of arterial PO_2 when gases are used for calibration. These factors, however, may not be related linearly to PO_2 , resulting in errors when high oxygen pressures are measured, as in samples obtained from a patient to whom pure oxygen is given to estimate the magnitude of a right-to-left shunt. The simplest approach would seem to be calibration of the electrode with solutions, rather than gases. This is probably true, but large differences have been found for the same instrument using samples of different test solutions equilibrated to the same PO_2 .²¹³ In general, the more the oxygen-carrying capacity of the solution approximates that of blood, the smaller is the error. Thus the large interinstrument variability of oxygen pressure values reported for blind samples tested in a quality-control program may not reflect the variability that would be achieved if all tests were run with blood equilibrated to the appropriate oxygen tensions. For a single machine, the range of repeated measurements of PO_2 in blood is 3.0 mm Hg for PO_2 values from 20 to 150 mm Hg.²¹⁰ In normal seated adult subjects, the predicted arterial PO_2 can be obtained from Mellemaard's data¹⁹⁷ with a SD around the regression line of approximately 6.0 mm Hg:

$$\text{PO}_2 = 104.2 - 0.27 \times \text{age (years)} \quad (46)$$

A final problem for some highly automated blood-gas machines appears only when samples of very high or very low PO_2 are tested. This is due to the error introduced by “contamination” of the sample chamber by the rinsing fluid.¹⁸⁵ If the PO_2 of the rinsing fluid is similar to that of room air, then the persistence of a small amount of fluid does not much alter the PO_2 measured for blood samples with oxygen pressures between 60 and 100 mm Hg. The PO_2 of the rinsing fluid affects the values recorded for samples with oxygen pressures at either extreme. If the design of the machine permits, this source of error can be reduced by flushing the sample chamber with a fluid that has a PO_2 near the estimated value of the sample or by introducing consecutive specimens without flushing the chamber.

OXYGEN CONTENT. Assessment of the adequacy of oxygen delivery requires not only measurement of the PO_2 in plasma but also measurement of the oxygen content in blood. Oxygen content, the sum of the oxygen bound to hemoglobin and that dissolved in plasma, can be measured directly by chemical or galvanic cell methods and can be estimated from the PO_2 , the total hemoglobin

concentration, and the percentage of oxyhemoglobin. The measurement or estimation of oxygen content of arterial and venous blood is required for calculating cardiac output by the Fick equation and for estimating the “shuntlike effect” in hypoxemic patients.

The chemical method for measuring total oxygen content involves liberating chemically bound oxygen and carbon dioxide from blood by adding ferricyanide, measuring the total quantity of gas displaced, and then absorbing the carbon dioxide with sodium hydroxide. This is the basis of the Van Slyke method, which served as the reference method for many years but is now used infrequently because of its demands on time and technical skill.²⁰⁸

Another method is the galvanic cell method, in which oxygen is chemically liberated from blood and transferred to a fuel cell, where a current is generated in proportion to the amount of oxygen delivered. This device yields values with an accuracy and precision similar to those obtained by the Van Slyke method.²¹⁴

The method used most commonly for calculating oxygen content is measurement of the total hemoglobin concentration by the cyanmethemoglobin method,²¹⁵ the percentage of oxyhemoglobin by a spectrophotometric method, and the dissolved oxygen as the product of arterial PO_2 and oxygen's solubility coefficient (0.003 mL per 100 mL blood).

Spectrophotometry is based on the discovery that substances differentially absorb various wavelengths of light. In the absence of other materials that absorb light at the same wavelength, the concentration of a substance in a solution is proportional to the amount of light absorbed. This method is especially applicable to hemoglobin analysis, because the various forms of hemoglobin (e.g., oxyhemoglobin, reduced hemoglobin, carboxyhemoglobin, sulfhemoglobin, methemoglobin) have characteristic spectra of light absorption. A simple two-wavelength spectrophotometer developed in 1900 could relate the amount of oxyhemoglobin to total hemoglobin but gave falsely high values when carboxyhemoglobin or methemoglobin was present. Three-wavelength instruments can simultaneously measure total hemoglobin, oxyhemoglobin, and carboxyhemoglobin; and a four-wavelength device is now marketed that enables measurement of methemoglobin as well.²¹⁵

The importance of measuring carboxyhemoglobin lies not just in quantifying correctly the proportion of nonreduced hemoglobin that is actually available for carrying oxygen but also in identifying a cause of a shift in the position of the oxygen-hemoglobin dissociation curve. The presence of carboxyhemoglobin increases the affinity of adjacent hemoglobin molecules for oxygen, so the curve is shifted to the left (i.e., less oxygen is unloaded from oxyhemoglobin at normal tissue PO_2). Similar disorders may result from inherited abnormalities in hemoglobin structure, as with hemoglobin Chesapeake, for which 50% desaturation does not develop until the PO_2 is lowered to 19 mm Hg, as opposed to the normal 50% unloading point of 27 mm Hg.

Direct measurement of the PO_2 at which 50% of the binding sites on hemoglobin are saturated (P_{50}) requires measurement of hemoglobin saturation after the blood sample is equilibrated at three oxygen pressures spanning the expected range (PO_2 values from 20 to 35 mm Hg are typical). Alternatively, a close estimate of PO_2 can be

drawn from single measurements of PO_2 and hemoglobin saturation.²¹⁵

Measurement of P_{50} is rarely needed in clinical practice. With the important exception of conditions in which carboxyhemoglobin is likely to be present in appreciable quantities (as in victims of fires or of exposure to closed-space combustion, or in heavy cigarette and cigar smokers), the estimation of blood oxygen content from measurements of arterial PO_2 and hemoglobin concentration usually provides sufficient information for decisions about clinical management.

Errors in the values used for such decisions arise most often from failures in the methods used for obtaining, transporting, and storing the sample of blood to be analyzed. For validity of the measurement, care must be taken to avoid contamination with room air or an excessive amount of anticoagulant when the sample is obtained, as well as leakage, diffusion, or consumption of gases while the sample is being transported and stored. For clinical utility, it is important that the sample be obtained with minimal discomfort and hazard. Syringes for *arterial blood gas* (ABG) collection are now designed to reduce the chance of a needle stick and to contain the optimal concentration of heparin.

Because of the adequacy of collateral flow in the event of occlusion of the sampled artery, the radial artery is the preferred site for obtaining the blood sample. However, in elderly patients and in patients with arteriosclerotic vascular disease, the adequacy of ulnar flow should be confirmed by the Allen test (appearance of palmar flush when the radial artery alone is decompressed). In infants, samples are most safely collected from the temporal or umbilical arteries. If radial and femoral arterial cannulation cannot be accomplished, then the brachial, axillary, and dorsalis pedis arteries should be considered. Sometimes physicians have been advised to avoid percutaneous cannulation of the brachial artery because of a lack of collateral vessels and the anatomic proximity to the median nerve. Aneurysm formation, thrombosis with loss of radial arterial pulse, and permanent median nerve neuropathy caused by hematoma have all been reported as complications of brachial cannulation. On the other hand, the literature associated with left heart catheterization states that percutaneous cannulation of the brachial artery is as “safe and effective” as surgical cutdown and arteriotomy.²¹⁶

Venous blood gases (VBG) are increasingly used as alternative samples to estimate systemic carbon dioxide and pH that do not require ABG sampling. Using VBG in the intensive care unit is particularly attractive because most critically ill patients have a central venous catheter from which it is easy to obtain VBG quickly.

VBG analysis can be performed on a central venous sample (central venous catheter), mixed venous sample (pulmonary artery catheter), or peripheral venous sample (venipuncture).

Central venous samples have been well correlated with ABGs. Venous pH, serum HCO_3^- , and PCO_2 are used to assess ventilator and acid base status; arterial oxygen saturation to guide resuscitation during septic shock; but partial oxygen pressure in mixed venous blood has no practical value because the tissues have already extracted oxygen before reaching the venous system.

The difference between VBG and ABG depends on the site of venous sampling; central venous pH is usually 0.03 pH units lower than ABG, PCO_2 4 to 5 mm Hg higher than ABG, and little or no difference in serum HCO_3^- .^{217,218} Mixed venous blood results are similar to central venous blood samples.^{219,220} Similar comparisons have been published for peripheral venous pH and ABG.²²¹⁻²²⁵

In clinical studies there is good agreement for pH and HCO_3^- between ABG and VBG in COPD patients, but not for PCO_2 or PO_2 . To avoid misleading results, clinicians should avoid VBG in hemodynamically unstable patients and rely on ABGs instead.²²⁶⁻²²⁸ If serial monitoring of critically ill patients is done routinely, VBG and ABG should be compared periodically. Widespread clinical use of VBG is limited because of the lack of validation studies on clinical outcomes.²²⁹

An alternative to arterial puncture is to obtain a sample of “arterialized” capillary or venous blood. The assumption is that the vasodilation produced by heat or by application of vasodilator cream to a region with low metabolic activity will result in delivery of such an excess of arterial blood that local metabolism causes only small changes in PO_2 , PCO_2 , and pH. Under these circumstances, analysis of capillary or venous blood should provide close estimates of arterial values. The sites most commonly used for capillary sampling are the earlobe in adults and children and the lateral margin of the foot in infants; for sampling of arterialized venous blood, a dorsal hand vein is most commonly used. From any of these sites, the values obtained correlate well with arterial pH and PCO_2 .²³⁰ The values for PO_2 are also accurate, except in patients with arterial hypotension or local reductions in flow to the sample site (as may develop with the vasoconstrictive response to severe hypoxemia), in newborns, and in patients with high arterial PO_2 (i.e., breathing oxygen-enriched gas mixtures).

Once the sample is obtained, it should be analyzed promptly or placed on ice to minimize the effects of continued cell metabolism on oxygen consumption. This is especially important for samples with very high white blood cell or platelet counts and in samples with PO_2 greater than 100 mm Hg.

However the sample is obtained, clinical interpretation of blood-gas values is possible only if the condition of the patient at the time of sampling is noted. Most important is a description of the oxygen pressure of the inspired gas mixture, but position, activity level, habitus, diet, and other factors can also influence arterial blood-gas values. Clearly, an excited or frightened patient may hyperventilate or breath-hold during arterial puncture. However, comparison with the values obtained from indwelling catheters shows that pain caused by arterial sampling does not routinely cause a change in alveolar ventilation.

Noninvasive Measurements

The appeal of an accurate, noninvasive means of assessing arterial blood-gas pressures is compelling, and several devices have been developed for transcutaneous measurement of oxygen saturation and pressure. Some devices already provide sufficiently accurate data on oxygen pressure to have been put into widespread clinical use. However, important physiologic and technologic barriers must be

overcome for the development of a useful device for measuring carbon dioxide content and pressure.

Oxygen

OXIMETRY. It was recognized more than 50 years ago that the principles of spectrophotometry could be applied to transcutaneous measurement of oxygen saturation in capillary blood by measuring the quantities of light at different wavelengths transmitted through or reflected from the earlobe. With dilation of local arterial vessels through application of heat or a vasodilating chemical (e.g., nicotine, alcohol), capillary oxygen saturation should approximate arterial oxygen saturation. Early ear oximeters were reported to give accurate data but were not widely accepted because of the practical difficulties in operating cumbersome instruments that were hard to calibrate, sensitive to changes in position, and likely to give unpredictable, unstable values.

The principle of oximetry depends on Beer's law, by which the amount of light absorbed by a solute in solution is related to the concentration of the unknown solute:

$$\text{Log} \frac{I_{\text{IN}}}{I_{\text{TR}}} = C_A \times d \times \epsilon_A \quad (47)$$

where I_{IN} is the quantity of incident light, d is the distance through which light passes, C_A is the concentration of the solute (e.g., hemoglobin), ϵ_A is the absorption coefficient, and I_{TR} is the amount of light transmitted through A , the substance containing the solute.

When light is passed through tissue from the oximeter, the tissues absorb most of the light, and the amount of light absorbed does not vary with the cardiac cycle. During the cardiac cycle, however, there is a small increase in arterial blood, causing an increase in absorption of light. By comparing absorption at the peak and trough of the arterial pulse, the nonarterial sources of absorption become irrelevant (eFig. 25-22).

The probe consists of two light-emitting diodes that emit light at specific wavelengths, usually 660 nm and 940 nm (eFig. 25-23). At these wavelengths the light absorption by oxyhemoglobin and by reduced hemoglobin is markedly different. A photodetector is placed across a vascular bed (finger, nose, or earlobe) from the light source. When the *ratios* (R) of pulsatile and baseline light absorption are compared at these two wavelengths, the ratio of oxyhemoglobin to reduced hemoglobin may be calculated:

$$R = \frac{\text{pulsatile absorbance (660)}}{\text{baseline absorbance (660)}} \div \frac{\text{pulsatile absorbance (990)}}{\text{baseline absorbance (990)}} \quad (48)$$

The relationship between R and oxygen saturation was determined experimentally because there is no known function relating these two variables. A calibration curve was created by having healthy subjects with previously measured amounts of methemoglobin and carboxyhemoglobin breathe various hypoxic gas mixtures designed to produce oxygen saturations between 70% and 100%.²³¹ A sample of arterial blood was obtained with each gas mixture, oxygen saturation was measured using a carbon monoxide oximeter (spectrophotometric hemoximeter), and the R value measured by the pulse oximeter was compared.

Because only two wavelengths are used, the pulse oximeter can measure only two substances, so it determines “functional saturation”:

$$\text{Functional saturation} = \frac{\text{oxyhemoglobin}}{\text{oxyhemoglobin} + \text{reduced hemoglobin}} \quad (49)$$

Pulse oximeters are accurate when oxygen saturation is between 70% and 100%,²³² but they may be inaccurate below that range. These devices may be misleading in the presence of abnormal hemoglobins (methemoglobin, carboxyhemoglobin, fetal hemoglobin), dyes (methylene blue, indocyanine green), increased bilirubin level, low perfusion states, anemia, increased venous pulsations, and external light sources.²³³

Continuous monitoring of oxygen saturation is considered the standard of care in operating rooms and recovery rooms.²³⁴ The limitation of oximetry is that it measures oxygen saturation, and the flattened shape of the upper portion of the oxygen-hemoglobin dissociation curve means that large changes in PO_2 result in small changes in arterial oxygen saturation. Oximetry is thus inherently insensitive to changes in PO_2 from the normal range that have diagnostic and clinical significance even if they do not result in important falls in oxygen delivery. The actual 95% confidence limits of $\pm 5\%$ for arterial oxygen saturation reported for oximetry make this limitation all the more important.

TRANSCUTANEOUS OXYGEN ELECTRODE. The basic idea of the transcutaneous electrode is that a small polarographic electrode can measure the oxygen pressure in a bubble of gas trapped over the skin. Because the PO_2 at the surface of unwarmed skin is near zero, the success of the transcutaneous oxygen electrode depends on producing enough local vasodilation to compensate for the arterial-capillary gradient and also for the further loss of oxygen due to skin metabolism and imperfect diffusion of oxygen through the skin layer. This degree of vasodilation is achieved by warming the skin to 42°C . The increase in temperature causes local vasodilation and displaces the hemoglobin dissociation curve to the right. Thus the oxygen pressure is increased for any blood oxygen pressure, partially correcting for the losses of oxygen between the arterioles and the skin surface.

The skin surface electrode developed by Huch and associates²³⁵ in 1973 has proved accurate in continuous measurement of transcutaneous PO_2 in both healthy and sick newborns. Not surprisingly, transcutaneous PO_2 most severely underestimates arterial PO_2 when skin perfusion is decreased from hypotension. Arterial PO_2 was also underestimated in infants treated with tolazoline for pulmonary hypertension, possibly because the general peripheral vasodilation caused by the drug exceeded the effect of the preferential local vasodilation intended from local heating of the skin. These problems have not prevented the application of this noninvasive device for regulating oxygen therapy or ventilatory assistance to infants with neonatal respiratory distress syndrome, for monitoring apnea, for sleep studies, or for analyzing the impact of nursery procedures on oxygenation. The technique is not as well accepted for estimating PO_2 in adults, in whom the greater thickness of skin impairs oxygen diffusion. Carter and Banham²³⁶ reported

that transcutaneous electrodes for measuring PO_2 and PCO_2 during exercise in adults with a variety of pulmonary disorders were reliable, provided the electrodes were kept at a slightly higher temperature (45°C) and the work rate intervals were gradual to allow for the slow response time. Unfortunately, most other workers have failed to confirm these findings,²³⁷ although the technique appears reliable for measuring the direction of change in arterial PO_2 in adult patients performing exercise^{238,239} or during sleep studies.

Carbon Dioxide

CAPNOGRAPHY. The noninvasive measurement of PCO_2 is as important as the measurement of PO_2 , especially in critical care units and operating rooms. The measurement of carbon dioxide during the respiratory cycle is called *capnometry*, and the display of the analog waveform is called a *capnogram* (eFig. 25-24). This measurement can be made using an infrared spectrometer, which is widely available. Care must be taken to calibrate the instrument regularly and to avoid interference by nitrous oxide, acetylene, and carbon monoxide.²⁴⁰ A mass spectrometer can be used to measure all the respiratory gases (carbon dioxide, oxygen, and nitrogen) as well as many anesthetic gases. This device is very rapid but very expensive. It is used most commonly in pulmonary and exercise laboratories and in operating rooms where sample gases from several patients may be tested in sequence. Capnography is valuable in detecting successful tracheal intubation versus esophageal intubation and in monitoring cardiopulmonary resuscitation. Capnography is also useful in detecting a variety of problems in ventilated patients, including an obstructed endotracheal tube, a disconnected airway, ventilator malfunction, severe pulmonary hypoperfusion, and pulmonary embolism.²⁴¹⁻²⁴³

The end-tidal carbon dioxide may decrease suddenly in a life-threatening situation such as ventilator malfunction or a disconnected airway, as illustrated in eFigure 25-25. The end-tidal carbon dioxide data may be misleading when dead space is increased (increased anatomic dead space, dead space added in series to the airway of the patient, abnormally increased respiratory rate). In these situations there is an increased difference between arterial and end-tidal carbon dioxide, and the end-tidal level does not plateau. When wasted ventilation is increased because of regional increased ventilation relative to perfusion (e.g., restrictive or obstructive ventilatory defects, parallel dead space, or pulmonary vascular obstruction), differences between arterial and end-tidal carbon dioxide are also increased. In these situations the alveolar plateau is present but abnormally reduced. The shape of the waveform may be diagnostic of pulmonary vascular obstruction (eFig. 25-26).

COLORIMETRIC END-TIDAL CARBON DIOXIDE. In some centers, colorimetric measurement is used instead of capnography or other devices to monitor end-tidal carbon dioxide in critical care units, recovery rooms, and operating rooms. The method appears to be as accurate and sensitive as capnography. Both techniques appear useful in the management of critically ill patients.²⁴⁴

TRANSCUTANEOUS CARBON DIOXIDE ELECTRODE. A device for transcutaneous measurement of PCO_2 has been developed. It also involves trapping gas above the skin layer, and

measuring carbon dioxide pressure by photometric analysis with infrared light.²⁴⁵ The device has a long time-constant, and skin preparation requires stripping of the stratum corneum. Although the values for transcutaneous PCO₂ correspond closely to those for arterial PCO₂ in healthy subjects, erroneous values manifest with decreased skin perfusion, edema, and obesity.²³⁶ This electrode does appear useful in long-term monitoring,²⁴⁶ but its use in evaluating carbon dioxide transfer during exercise in adults is still controversial.²³⁷

New Technologies

Even at the bedside, in vitro blood-gas analysis requires limitation of the frequency of serial blood-gas measurements for two major reasons: blood loss and cost. Therefore a second major area of development involves in vivo or ex vivo blood-gas analyzers.²⁴⁷ These analyzers make it possible for the measurements to be made continuously, or as frequently as deemed desirable, without permanently removing blood or adding cost.²⁴⁸

So-called on-demand blood-gas monitors locate the sensors extravascularly but within the radial artery line, thereby avoiding the problems associated with intravascular measurements. Extravascular on-demand blood-gas analysis appears accurate, allows monitoring of trends of blood-gas changes, and decreases the risk for infection, the therapeutic decision time involved, and blood loss. However, until large patient studies are available, the clinical role of online blood-gas analysis cannot be clearly delineated.²⁴⁹

The successful relocation of blood-gas measurements from the standard clinical laboratory to a combination of blood-gas monitors and point-of-care analyzers at the bedside could change the practice of acute care medicine as did the introduction of laboratory-based blood-gas analysis more than 30 years ago. Therefore it is crucial for pulmonologists, intensivists, and their colleagues to be certain that these devices are accurate, reliable, and cost beneficial to avoid widespread application of yet another set of new technologies that provide more data, greater costs, and only questionable patient benefits.^{250,251}

Table 25-2 Severity of Pulmonary Impairment²²⁹

Impairment	FEV ₁ [*]	TLC [†]	VC [†]	DL _{CO}
Normal	±95% CI	±95% CI	±95% CI	±95% CI
Mild	<LLN and ≥70	<LLN and ≥70	<LLN and ≥70	<LLN and ≥60
Moderate	60–69	<70 and ≥60	<70 and ≥60	<60 and ≥40
Moderately severe	50–59		<60 and ≥50	
Severe	35–49	<60	<50 and ≥35	<40
Very severe	<35		<35	

*Airflow obstruction is based on a decreased FEV₁/VC ratio. If the ratio is decreased below the lower 95% confidence interval (CI), the severity of airflow is graded on the percent predicted FEV₁.

†Pulmonary restriction is based on decreased TLC. If TLC is not available, a reduction in VC without a reduction in the FEV₁/VC ratio is a "restriction of the volume excursion of the lung."

CI, confidence interval; DL_{CO}, carbon monoxide diffusion in the lung; FEV₁, forced expiratory volume in 1 second; LLN, lower limit of the 95% confidence interval; TLC, total lung capacity; VC, vital capacity.

In patients with neither a restrictive nor an obstructive ventilatory defect, the finding of an isolated decreased single-breath DL_{CO} may be the first clue to the presence of an interstitial process, emphysema, or pulmonary vascular obstruction. In general the degree of severity of a particular pulmonary pattern is indicated by the decrease in percentage of predicted values, illustrated in Table 25-2.

If the screening test results are normal but the patient has symptoms, more complete pulmonary function studies are indicated. Such a diagnostic approach is essential if the ABG levels reveal evidence of chronic hyperventilation. Chronic hyperventilation (decreased arterial PCO₂ with evidence of renal compensation and a near-normal arterial pH) is observed in several major pulmonary disorders, probably reflecting an abnormal ventilatory drive.^{253–255} In patients with cough or with a history of wheezing with respiratory tract infections, bronchial provocation testing can determine whether the patient has abnormal airway responsiveness. If the patient complains of effort dyspnea or fatigue, particularly if the symptoms have caused a significant change in lifestyle and the screening tests do not explain the symptoms, an exercise test is indicated (see Chapter 26).

PATTERNS OF RESPONSE

Obstructive Ventilatory Defects

Airway obstruction is characterized by a decrease in flow (Table 25-3). Supplementary data confirming obstruction include increased RV and RAW, uneven distribution of ventilation, and significant reversibility of airway obstruction, with or without decreased diffusing capacity. It is noteworthy to point out that some patients with normal lungs may have a decrease in the lower limits of normality for the FEV₁/FVC ratio with a normal FEV₁, and all other measured parameters may be normal. In this situation, this would be considered a normal variant.²⁵⁶ Alternatively, if this pattern

Table 25-3 Obstructive Ventilatory Defect

CHARACTERISTICS OF OBSTRUCTIVE VENTILATORY DEFECT
Decreased maximum expiratory airflow
Decreased MVV
Normal or decreased VC
SUPPLEMENTAL DATA CONFIRMING OBSTRUCTION
Increased RV
Increased airway resistance
Abnormal distribution of inspired gas
Significant response to bronchodilator
Decreased DL _{CO}
Decreased lung elastic recoil

DL_{CO}, diffusing capacity of the lung for carbon monoxide; MVV, maximal voluntary ventilation; RV, residual volume; VC, vital capacity.

Adapted from Welch MH: Ventilatory function of the lungs. In Guenter CA, Welch MH, editors: *Pulmonary medicine*, Philadelphia, 1977, JB Lippincott, pp 72–123.

is observed in a subject with curvilinearity of the flow-volume curve, accompanied by other patterns suggesting airway obstruction, this could suggest early airway obstruction.

Because of the increased incidence of obesity in the United States, it is important to be aware of the deleterious effect of obesity on patients with airflow obstruction. In addition, the increased mass of the chest wall decreases expiratory reserve volume, subsequently FRC, and then TLC. As the expiratory volume in reserve diminishes, tidal volume is shifted toward RV, graphically depicted when the tidal volume loop is superimposed on the flow-volume loop. As the patient breathes at lower lung volumes, RAW increases, (A–a)PO₂ differences increase, and respiratory symptoms increase. This situation is worsened in the supine posture. These effects of obesity are particularly limiting in patients with airflow obstruction. (see Chapter 98)

Reversibility. Another approach to the differential diagnosis of the obstructive pattern is the assessment of reversibility of impaired expiratory airflow. Reversibility may appear acutely in response to administration of bronchodilator aerosols, chronically in response to a variety of airway treatments, or spontaneously during remission of bronchial asthma. Reversibility implies a better prognosis than fixed obstruction and may have considerable significance in planning a treatment program.

The ATS recommends that VC (slow or forced) and FEV₁ be the primary spirometric indices used to determine bronchodilator response.⁶ Total expiratory time should be considered when using FVC to assess the dilator response because, in obstructed patients, FVC increases when expiratory time increases. A 12% increase above the prebronchodilator value and a 200-mL increase in either FVC or FEV₁ indicate a positive bronchodilator response in adults. FEF_{25%–75%} and instantaneous flow rates should be considered only secondarily in evaluating reversibility. They must be volume-adjusted, or the effect of changing FVC must be considered in the interpretation (Fig. 25-17). Ratios such as FEV₁/VC should not be used to evaluate reversibility.

Eliasson and Degraff²⁵⁷ reported that these conventional criteria may still be misleading. In their study these criteria were not useful for distinguishing patients with asthma from those with other forms of chronic airway obstruction

Figure 25-17 Schematic illustration of volume adjustment to calculate the isovolume $FEF_{25-75\%}$ or forced expiratory flow between 25% and 75% of forced vital capacity. Left, Before administration of bronchodilator, the $FEF_{25-75\%}$ is calculated from a line connecting two points on the volume-time curve of the forced vital capacity (FVC). One solid circle indicates when 25% of the FVC is exhaled (6.5 L), and the other solid circle indicates when 75% of the FVC is exhaled (3.5 L). This volume change (3.0 L) develops in 3.4 seconds, so the $FEF_{25-75\%}$ is 0.88 L/sec. Right, After administration of bronchodilator, one open circle indicates when 25% of the FVC is exhaled (6.0 L), and the other open circle indicates when 75% of the FVC is exhaled (2.0 L). This volume change develops in 1.3 seconds, so the $FEF_{25-75\%}$ is 3.0 L/sec. The values based on the “before” volumes from the pretreatment curve (solid circles) have been extended to the posttreatment (“after”) curve. The volume-adjusted or isovolume $FEF_{25-75\%}$ is determined from a line connecting the solid circles on the “after” graph. In this case the volume change is the same as that observed in the “before” graph, or 3.0 L, but it took place in only 0.6 second, so the isovolume $FEF_{25-75\%}$ is 5.0 L/sec, a marked improvement induced by the bronchodilator. This approach was developed because early reports indicated that some patients appeared to have significant improvement in forced expiratory volume in 1 second (FEV_1) but not in $FEF_{25-75\%}$ when no volume adjustment was made in the calculation of $FEF_{25-75\%}$. When a volume adjustment was made in the calculation of $FEF_{25-75\%}$ there was improvement in both FEV_1 and $FEF_{25-75\%}$ as illustrated.

in a clinically defined population. Furthermore, when applied to a patient population, they resulted in selection of the most obstructed patients (a contradiction of the definition of reversibility). Instead, these authors suggested that the difference in FEV_1 before and after bronchodilator administration (expressed either as an absolute value or as a percentage of predicted FEV_1) appeared more appropriate as an expression of reversibility. Their study indicated that, when one compares results from two different bronchodilator studies, careful attention must be paid to the definitions of patient populations, the definitions of obstruction and reversibility, the degree of obstruction present, and the methods used to calculate bronchodilator response. Jain et al²⁵⁸ studied 321 physician-diagnosed asthmatic patients and found a significant proportion had increased RV and abnormal RV/TLC ratio in the presence of normal FEV_1 /FVC ratio and no significant bronchodilator response.

Failure to demonstrate significant responses to acute bronchodilator therapy does not rule out reversible airway obstruction. Many reports confirm that asthmatic patients with completely reversible airway obstruction may initially fail to respond to inhaled bronchodilators.²⁵⁹

In fact, one of the pharmacologic benefits attributed to corticosteroids in this situation is that they enhance responsiveness to β -adrenergic agonists.²⁶⁰ We have observed that many patients with severe chronic airflow obstruction are undertreated with the usual treatment regimens. These patients show significant bronchodilation during exercise and in response to increased β -adrenergic treatment.

Bronchial Provocation. Provocation tests may be extremely useful in the diagnosis and management of

patients with asthma or occupational asthma and in the differential diagnosis of patients with chronic cough, wheezing, or intermittent dyspnea. Although many laboratories use spirometry to evaluate the airway response, measurement of RAW in a body plethysmograph is more sensitive, more specific for abnormalities in airway tone, and usually easier for the patient to perform than tests that depend on inspiration to TLC followed by a forced exhalation. In limited numbers of patients, tests with specific allergens may be helpful in the evaluation of allergic asthma. Similarly, in a small number of patients suspected of having occupational asthma, specific challenge with agents found in the workplace may be useful in the diagnosis. However, the referring physician should be aware that these challenge tests are dangerous and tedious, usually require hospitalization for observation, and may not be useful if the patient is exposed to multiple agents in the workplace. (When multiple agents are involved, provocation testing for each agent is usually not practical because it would require many weeks and repeated hospitalizations at great expense to assess each and every agent at multiple concentrations or doses [see Chapter 72].)

Tests of Nonspecific Airway Responsiveness. Abnormal airway responsiveness is viewed by many as a characteristic feature of asthma. It may also be found in patients with chronic bronchitis and cystic fibrosis. Although a variety of stimuli have been used, including exercise and eucapnic ventilation, the most common stimuli are histamine and methacholine. Responses to these stimuli have good correlation and reproducibility.²⁶¹ These agents are delivered in incremental concentrations until a desired

Obstructive Ventilatory Defects

Reversibility. Inhalation of albuterol (180 µg) 10 to 20 minutes before spirometry testing is used in many laboratories to test reversibility. Because many patients with asthma or other forms of airway disease do not respond initially to β -adrenergic agonists, particularly at low doses, it is worth considering evaluation of reversibility after administration of ipratropium bromide aerosol (36 µg). However, the maximal effect of ipratropium bromide may take 30 to 45 minutes. Furthermore, many patients with reversible airway obstruction do not respond to a standard clinical dose of either class of dilator, but airway obstruction still reverses completely if they are treated with larger doses. Thus, in some patients with airway obstruction who have never been treated before and who do not respond to a standard clinical dose of inhaled dilator, we often administer a cumulative dose-response protocol. Spirometry is measured before (baseline) and 15 minutes after administration of progressively increasing doses of albuterol (180 µg) or ipratropium bromide (36 µg) aerosol. The aerosol is administered every 15 minutes until a maximal increase in FEV₁ or FVC is attained or limiting symptoms are reached. In this time interval, both agents produce at least 80% of their maximal response, and most patients respond maximally after receiving 8 to 10 puffs.

effect on pulmonary function is achieved; usually, less than 0.1 mg/mL is the initial concentration to avoid inducing an inordinately severe reaction.

FEV₁ is the most common test used to evaluate the outcome of this procedure, although specific RAW may be more sensitive. Medications, baseline airway function, respiratory infections, and exposure to specific allergens and chemical sensitizers influence responses. Bronchodilators, antihistamines, and other agents that decrease bronchial responsiveness should be withheld before the test.²⁶²

Compared to methacholine and histamine, which have *direct* effects on airway smooth muscle to cause airway narrowing, so-called *indirect* challenge tests (which cause airway narrowing indirectly by triggering mast cell degranulation by osmotic stimuli, or mediator release from inflammatory cells) may have an important place in the assessment of asthma. Such indirect challenge tests (including exercise-induced bronchoconstriction, eucapnic voluntary hyperpnea, hypertonic and hypotonic aerosols, and mannitol) are useful for monitoring treatment with inhaled corticosteroids.²⁶³ Indirect tests identify subjects with the potential for exercise-induced bronchoconstriction and therefore are useful for members of the armed services, firefighters, police, and elite athletes. A positive indirect test result suggests that inflammatory cells and their mediators are present in sufficient numbers and concentration to indicate that asthma is active at the time of the test. A negative test result in a known asthmatic patient means good control or mild disease. Healthy subjects do not experience bronchoconstriction during the indirect tests.²⁶³

Although histamine and methacholine are well-established agents for identifying airway hyperresponsiveness, the response to these agonists is not specific for the diagnosis of asthma. Both agents are better at excluding the diagnosis of asthma than making the diagnosis. Furthermore, neither agonist can establish or exclude the diagnosis of exercise-induced asthma, so they are not appropriate for assessment of persons at occupational risk or of athletes. Identification of airway hyperresponsiveness by pharmacologic agents does not indicate who will respond to inhaled corticosteroids, nor does it distinguish between the effects of different doses of steroids. Many asthmatic patients remain reactive to histamine and methacholine long after treatment, so airway hyperresponsiveness is not useful as a guide to withdrawal from steroid treatment.

According to Anderson and Brannan,²⁶³ dry powder mannitol can identify those patients with exercise-induced asthma who will respond to inhaled corticosteroids. A positive response to mannitol depends on activation of mast cells secondary to osmotic changes in the airways, release of leukotrienes and other mediators, and development of active inflammation in the airways.²⁶³ If the mannitol response is positive, sufficient numbers of inflammatory cells are present to release enough mediators to cause bronchoconstriction. The response to mannitol is reduced by corticosteroid therapy and may disappear within 6 to 8 weeks. Thus mannitol responsiveness may be able to predict the risk for a clinical flare during reduction of the corticosteroid dose. Mannitol alone may be able to identify those patients who will respond to inhaled corticosteroids and also (in patients already treated with corticosteroids) serve to guide the reduction of the steroid dose.²⁶⁴⁻²⁶⁸

Tests of Specific Airway Responsiveness. Incremental allergen concentrations are given sequentially until the desired pulmonary function change develops. The response to inhaled allergen depends on both allergic sensitivity, as reflected by skin test, and nonspecific airway responsiveness, as reflected by histamine or methacholine responsiveness.

Objective Evaluation of Lung Function in Management of Asthma. Peak flowmeters play a very important role in National Institutes of Health–based guidelines for proper asthma management. Peak flowmeters offer advantages of convenience and portability; however, peak flowmeters are also less reproducible than standard spirometry. Thus it is critical that physicians recognize the importance of the use of spirometers in the initial assessment of the patient suspected of having asthma and in periodic monitoring of the management program.

According to the National Institutes of Health guideline for the diagnosis and management of asthma (Expert Panel Report No. 2, 1977), “spirometry measurements (FEV₁, FVC, FEV₁/FVC) before and after the patient inhales a short-acting bronchodilator should be undertaken for patients in whom the diagnosis of asthma is being considered.”²⁷¹ Office-based physicians caring for asthma patients should have access to spirometry, which is useful both in diagnosis and in periodic monitoring of airway function. When office spirometry shows severe abnormalities or if questions arise regarding test accuracy or interpretation, the Expert Panel recommends further assessment in a specialized pulmonary function laboratory.

These objective measurements of pulmonary function (e.g., peak flow, spirometry) are necessary for the diagnosis of asthma because the medical history and physical examination do not reliably exclude other diagnoses or characterize the lung impairment. Physicians seem to be able to identify the presence of airflow obstruction,²⁷² but they have a limited ability to assess the degree of obstruction²⁷³ or to predict whether it is reversible.²⁷² Furthermore, large segments of our population, particularly older adults, appear to have undiagnosed airflow obstruction and also undiagnosed asthma. These patients are neither detected nor diagnosed properly without spirometric assessment.^{274,275,275a}

Bullous Lung Disease. In certain obstructive ventilatory defects, a variety of specific tests may prove useful. For example, in a patient with a localized bulla who is being considered for surgical resection of the lesion, it is important to show that the bulla, and not intrinsic airway disease or emphysema, is responsible for the pulmonary function abnormalities and disability. An exercise study can quantify the disability caused by the bulla or associated disease. Physiologic studies relating RAW and V_{max} to static PL can differentiate the effects of loss of lung elastic recoil from those of intrinsic airway disease. Radioisotope perfusion lung scans, pulmonary angiograms, and thin-section CT scans can determine whether the vascular defects are localized (i.e., bullae) or diffuse (i.e., emphysema). These studies may also indicate whether the bulla is compressing normal lung tissue. This possibility can be confirmed by a shunt study to determine whether compression of normal lung

The nonspecific airway challenge begins with a diluent control aerosol, and responses are reported relative to the diluent value. The dose of agonist is expressed on the logarithmic abscissa as (1) cumulative inhalation breath units (the equivalent of one breath of a concentration containing 1 mg/mL); (2) cumulative amount of agonist (in micro-moles) delivered from the nebulizer; and (3) the concentration inhaled (in milligrams per milliliter). The end point is the dose causing a decrease in FEV₁ of 20% or a decrease in specific airway conductance of 40%. Pulmonary function measurements should be made 3 to 5 minutes after delivery of the aerosol and repeated in 5 minutes.

Most commercial allergens are obtained as lyophilized extracts or as concentrated solutions. These retain potency indefinitely when stored at -20°C . Thus the original guidelines of a starting concentration of *ragweed pollen extract* (AgE) that produces a 2+ reaction (larger than a 5-mm

wheal) after intradermal injection is probably safe but may result in many doses having to be delivered in some patients. With a 2+ skin test at 0.0005 μg AgE/mL, an aerosol of 0.025 μg AgE/mL is used; with a 2+ skin test at 0.005 μg AgE/mL, an aerosol of 0.05 μg AgE/mL is used; and with a 2+ skin test at 0.05 μg AgE/mL, the same concentration of AgE is used in the aerosol challenge.

Aerosol delivery in North America is usually by (1) intermittent generation of aerosol during inspiration from a DeVilbiss 646 nebulizer connected to a dose-metering device that controls flow of compressed air at 20 psi for a fixed time, at a flow rate of 750 mL/min or less²⁶⁹; or (2) by a Wright nebulizer with aerosol delivered to a face mask with a nebulizer output of 0.13 to 0.16 mL/min.²⁷⁰ Respiratory rate, tidal volume, and inspiratory flow rate are kept constant for a fixed time interval, and the volume of aerosol solution administered is 3 mL.

tissue by the bulla is having a shuntlike effect on arterial PO_2 . Radioisotope ventilation lung scans also help determine whether the ventilatory defects are localized (i.e., bullae) or diffuse (i.e., emphysema). The single-breath DL_{CO} is useful for detecting decreased numbers of pulmonary capillaries, reflecting the presence of pulmonary emphysema. Measurement of “trapped gas” by comparison of TLC measured by single-breath gas dilution and by body plethysmography should provide an estimate of the size of the bulla. This same multipronged approach may be useful for evaluating patients with advanced emphysema before consideration for possible surgical treatment (see later discussion).

Emphysema: Lung Volume Reduction Surgery

Lung volume reduction surgery (LVRS) for emphysema, first introduced by Brantigan²⁷⁶ in 1954, is based on the theory that reduction in lung volume in patients with diffuse emphysema improves lung elastic recoil, increases radial traction on bronchi, and thus increases expiratory flow and relieves dyspnea. After initial disappointing results, this approach was revived as a therapy for COPD in the early 1990s, but it was not until Cooper and Patterson²⁷⁷ reported their first 20 operations using the sternotomy approach in 1995 that enthusiasm for LVRS increased dramatically.

The conventional explanations for the beneficial effects of LVRS are the increased elastic recoil at TLC²⁷⁸ and increased ability of inspiratory muscles to generate force.²⁷⁹ An important concept concerning the mechanism of LVRS was proposed by Fessler and Permutt.²⁸⁰ They developed a mathematical analysis and graphic model of the mechanism of improvement in both VC and expiratory airflow, based on their concept of the interaction between lung function and respiratory muscle function. They extended their analysis from LVRS to previously published data on mechanical properties of the lungs in patients with α_1 -antitrypsin deficiency, COPD, and asthma. In each of these diseases, a major determinant of airflow limitation is the ratio of *residual volume to total lung capacity* (RV/TLC). Their analysis suggested that RV/TLC determines the improvement in pulmonary function following surgical treatment of emphysema. Regardless of the underlying disease, impaired airflow appears to be due to the mismatch between the size of the lung and the size of the chest wall; surgical resection of lung tissue improves the matching. Fessler and Permutt also suggested that their analysis can be used to guide patient selection for LVRS.

Thus, when LVRS improves airflow limitation, it does so by improving the fit between lungs and chest wall by decreasing RV more than TLC. Although increased elastic recoil at TLC and increased ability of inspiratory muscles to generate force are the conventional explanations for the beneficial effects of LVRS, neither of these factors would necessarily increase VC as well as FEV_1 .

This analysis demonstrates that, regardless of the cause of increased RV (emphysema, increased airway closing pressure, or a normal lung contained in a chest wall that is too small), LVRS improves FEV_1 . The level of RV/TLC is of greater importance than the specific cause of the increased RV/TLC ratio. Furthermore, there is little difference in improvement in FEV_1 whether the surgeon removes completely nonfunctional lung tissue or tissue with the same

function as the lung left behind. The implications for selection criteria are straightforward: if increased FEV_1 is the goal of LVRS, then the optimal candidates are those with the highest RV/TLC. Finally, the critical factor in comparing outcomes among patients, procedures, or centers is the amount of lung removed, which cannot be estimated accurately by weighing the resected specimens. Fessler and Permutt²⁸⁰ suggested that the best measurement of the fraction of lung resected may be derived from the ratio of residual volumes: $1 - RV_A/RV_B$, where RV_A is the residual volume before LVRS and RV_B is the residual volume after LVRS. Several studies have examined the mechanisms responsible for improved function in these patients. Fessler and associates²⁸¹ studied 78 patients and found that the results supported their model, as discussed previously; that is, RV/TLC is an important predictor of improvement in FVC because it reflects the mismatch in size between the hyperinflated lungs and the surrounding chest, and increased FVC is an important determinant of increased FEV_1 after LVRS. Ingenito and associates²⁸² performed an elegant study of 37 patients undergoing LVRS and found that increased FEV_1 (increased by $28\% \pm 44\%$) correlated closely with increase in maximal flow of $78\% \pm 132\%$. The increased expiratory flow was largely due to increased lung recoil pressure, and FEV_1 improved without changes in small airway conductance, airway closing pressure, or lung compliance. These results support the Fessler and Permutt concept that “resizing of the lung to the chest wall” is the primary mechanism by which LVRS improves function. In another study, Mineo and colleagues²⁸³ showed dramatic improvement in right heart function during exercise following LVRS; furthermore, the improvement in right ventricular ejection fraction during exercise correlated closely with the change in RV/TLC ratio, also supporting the Fessler and Permutt theory.

In a review of respiratory muscles, Laghi and Tobin²⁸⁴ strongly supported the Fessler and Permutt concept. They argued that an imbalance between hyperinflated lungs and a relatively small rib cage was primarily responsible for abnormal respiratory muscle function in patients with COPD; therefore reducing the volume of the lungs improves the match between the lungs and rib cage, and thereby the capacity of the respiratory muscles to generate pressure. They noted that most patients undergoing LVRS show improved expiratory flow and less hyperinflation and air trapping. These effects result from increased lung elastic recoil and better matching of lung and rib cage size, which also leads to decreased respiratory pressure required for tidal breathing and decreased cost of carbon dioxide removal. The mechanisms responsible for these benefits include improved alveolar ventilation, decreased operating lung volumes, decreased dynamic positive end-expiratory pressure, and decreased dynamic lung and chest wall stiffness. According to Laghi and Tobin, the surgery also improves the length-tension relationship of the respiratory muscles. They also noted improved coupling between inspiratory effort and output of the diaphragm, which correlated closely with improved 6-minute walk test results.

Long-term benefits are more difficult to identify. Improved FEV_1 appears to peak at 3 to 6 months and then declines 100 to 150 mL or more over the subsequent year. Improvement in TLC and RV may be more stable in the first year.

Table 25-4 Restrictive Ventilatory Defect

CHARACTERISTICS OF RESTRICTIVE VENTILATORY DEFECT

Decreased VC
Relatively normal expiratory flow rates
Relatively normal MVV

SUPPLEMENTAL DATA CONFIRMING RESTRICTIVE PATTERN

Decreased TLC
Decreased lung compliance
Chronic alveolar hyperventilation
Increased (A-a)PO₂
Abnormal distribution of inspired gas

(A-a)PO₂, alveolar-arterial PO₂ difference; MVV, maximal voluntary ventilation; TLC, total lung capacity; VC, vital capacity.

Adapted from Welch MH: Ventilatory function of the lungs. In Guenter CA, Welch MH, editors: *Pulmonary medicine*, Philadelphia, 1977, JB Lippincott, pp 72-123.

Gelb and associates²⁸⁵ reported that FEV₁ decreased 141 ± 60 mL per year over 3.8 ± 1.2 years following surgery. Obviously, many more long-term data are needed before it is clear whether this procedure is useful in treatment of COPD.^{286,287}

Restrictive Ventilatory Defects

A parallel decrease in FEV₁ and FVC with a normal or increased FEV₁/FVC ratio suggests a restrictive defect, but this diagnosis requires a decreased TLC by plethysmograph or multiple-breath dilution method. Supplementary data confirming restriction include decreased single-breath DL_{CO}, uneven distribution of ventilation, chronic alveolar hyperventilation, and increased (A-a)PO₂ (Table 25-4). Because static lung elastic recoil pressure depends on lung volume, the diagnosis of a restrictive ventilatory defect does not usually require measurement of pressure-volume curves of the lung. In patients with mixed disease or in whom poor cooperation is suspected, measurement of pressure-volume curves may be helpful.

Pulmonary function tests have been widely accepted and used in the management of interstitial lung diseases. Although the tests performed have changed little over the past several decades, extensive literature has been published highlighting their clinical role in the diagnosis, staging, prognosis, and follow-up of patients with a wide variety of interstitial lung diseases. Pulmonary function testing aids in the evaluation and management of patients with interstitial lung disease. Such function tests can provide a baseline estimation of prognosis and can be used to monitor disease progression and response to therapy. The FVC and DL_{CO} are the most valuable serial measurements,^{288,289} but further data are required to examine composite scoring and exercise gas exchange.²⁹⁰

Two groups have tried to develop a systemic approach to improving the initial evaluation of these patients. Wells and colleagues²⁹¹ of Brompton Hospital developed a composite physiologic index using DL_{CO}, FVC, and FEV₁, which is designed to reflect the morphologic extent of pulmonary fibrosis, with the goal of excluding confounding emphysema in patients with pulmonary fibrosis. Survival of 106 patients with pulmonary fibrosis was predicted more closely by the composite index than any single pulmonary function test. King and associates²⁹² collated their extensive

experience with interstitial lung disease at the National Jewish Medical and Research Center in a new scoring system and survival model for interstitial lung disease. They reviewed 238 patients with usual interstitial pneumonia confirmed by biopsy to develop a scoring system that would predict survival in newly diagnosed patients, based on clinical, radiologic, and physiologic data. In contrast to the Brompton index, the National Jewish Medical and Research Center system found that pulmonary function data contributed 45% of the score as follows: DL_{CO}/VA, 5%; (A-a)PO₂ at rest, 10%; and gas exchange during exercise, 30% (of which arterial PO₂ during exercise contributed 10.5%). Thus King and colleagues found that arterial hypoxemia is the most important single factor limiting exercise in these patients.

Three large referral centers have published qualitatively similar observations: a decrease in pulmonary function, especially FVC, with elapsed time after referral to the tertiary center predicts decreased survival in patients with idiopathic pulmonary fibrosis.^{290,293-295} Apparently, the changes in pulmonary function as early as 6 months after referral, rather than baseline pulmonary function or histopathologic characteristics, are of critical importance with respect to ultimate outcome. Future studies are essential to determine the specific features of patients with idiopathic pulmonary fibrosis who experience varying rates of deterioration with time, hopefully to understand the mechanisms involved and to improve treatment. (For comparison with other patterns of abnormal function, see Table 25-5.)

Mixed Obstructive and Restrictive Ventilatory Defects

This pattern of pulmonary function defect is not common; however, the ATS guidelines do not provide suggestions for how to assess the components of a mixed ventilatory defect separately. It is logical to assume that using the FEV₁ percentage predicted to grade the severity of obstruction in a mixed disorder will overestimate the severity due to the concomitant loss of volume contributed by restriction. A study by Gardner²⁹⁶ and coworkers has begun to address this issue by adjusting the FEV₁ percentage predicted for the degree of restriction. They accomplished this by dividing the FEV₁ percentage predicted by the TLC percentage predicted. In their cohort of 199 subjects with a mixed ventilatory defect, using the *adjusted* FEV₁ percentage predicted, they classified 33% with severe or very severe obstruction, whereas, using the *unadjusted* FEV₁ percentage predicted, they classified 76% in this category.²⁹⁶ They also showed that the correlation between the adjusted FEV₁ percentage and RV/TLC was better than with the unadjusted FEV₁ percentage. Because this work has not been validated, there is no widespread consensus on its use in clinical practice; however, it is important for the clinician to be cognizant of the possibility of overestimating the severity of obstruction in a patient with a mixed physiologic defect.

Pulmonary Vascular Obstruction

Patients who have dyspnea during exertion, especially those with decreased DL_{CO} without evidence of obstructive or restrictive ventilatory defects, deserve detailed pulmonary function studies of the pulmonary circulation. These studies should include exercise tests, especially when signs of

*Volumes are decreased in the presence of primary pulmonary hypertension but not chronic thromboemboli.

A, often absent; N, normal; (N), occasionally normal; ⇒, to; ↑, increased; ↓, decreased. Cdyn_L, dynamic compliance of the lung; CHF, congestive heart failure; Cst_L, static compliance of the lung; DL_{CO}, diffusing capacity of the lung for carbon monoxide; DLVA, diffusing capacity of the lung/alveolar volume; FEF, forced expiratory flow; FEF₅₀, forced expiratory flow after 50% of vital capacity exhaled; FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity; MEP, maximal expiratory pressure; MIP, maximal inspiratory pressure; MVV, maximal voluntary ventilation; PaCO₂, arterial PCO₂; PaO₂, arterial PO₂; PEF, peak expiratory flow; Pst_{max}, maximal static pressure; PVO, pulmonary vascular obstruction; RAW, airway resistance; RV, residual volume; SaO₂, arterial oxygen saturation; TLC, total lung capacity.

pulmonary hypertension are absent and radiographic methods fail to demonstrate obstruction of large pulmonary arteries. In fact it is important to make the diagnosis of pulmonary vascular obstruction before the development of pulmonary hypertension if possible. Measurements of V_D/V_T may be normal at rest but increased during exercise, indicating ventilated but poorly perfused regions of lung. The diagnosis of pulmonary vascular obstruction may be made by V_D/V_T measurements during exercise provided that no V_A/Q̇ abnormalities exist as a result of restrictive or obstructive ventilatory defects. Pulmonary vascular obstruction may cause abnormalities in V_D/V_T *only* during exercise, for several reasons. At rest, poorly perfused regions may be poorly ventilated; during exercise, ventilation may increase if deep breaths overcome smooth muscle constriction in peripheral airways.²⁹⁷ At rest, bronchial blood flow may maintain normal carbon dioxide output from a poorly perfused region; during exercise, the collateral blood flow may not be able to increase proportionately to ventilation. At rest, narrowed pulmonary arteries may perfuse poorly ventilated regions; with exercise, blood flow may fail to increase as much as the ventilation.

ABGs should be studied because most patients with pulmonary vascular obstruction appear to have an abnormal drive to ventilation, resulting in tachypnea and alveolar hyperventilation at rest and during exercise.^{297a} This abnormal drive results in decreased arterial PCO₂ and partially compensated respiratory alkalosis. Arterial PO₂ should be measured; in many patients with pulmonary vascular obstruction, arterial PO₂ may be normal at rest but decreased during exercise (eTable 25-2). Breathing pure oxygen allows the determination of the presence of a right-to-left shunt, which is often dependent on posture or exercise. The shunt tends to increase under conditions that increase right-sided pressures relative to left-sided pressures, as during increased venous return during exercise, in the supine posture, or at high versus low lung volumes.

“Poor Cooperation” Pattern

Pulmonary function tests in general depend heavily on the cooperation of the subject being tested. If a competent technician performs the procedures and recordings of the test tracings accompany the measurements, it is usually possible to determine the validity of the data. In some instances,

eTable 25-2 Effects of Exercise, Respiratory Maneuvers, and Posture on Arterial PO₂ (mm Hg) During Inhalation of Pure Oxygen

Case no.	SITTING ARTERIAL PO ₂				SUPINE ARTERIAL PO ₂

Table 25-6 Poor Cooperation

CHARACTERISTICS OF POOR COOPERATION

Decreased vital capacity
Relatively normal expiratory airflows (increased FEV₁/FVC ratio)

SUPPLEMENTARY RESULTS CONFIRMING PATTERN

Decreased total lung capacity
Decreased maximal static transpulmonary pressure
Uneven, slurred, irregular recording of spiograms

FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity.
Adapted from Welch MH: Ventilatory function of the lungs. In Guenter CA, Welch MH, editors: *Pulmonary medicine*, Philadelphia, 1977, JB Lippincott, pp 72–123.

particularly in cases involving financial compensation, the pulmonary function tests must be carried out as part of a complete clinical evaluation, and the evaluating physician involved must observe the test results generated. Nevertheless, “poor cooperation” can usually be identified on the basis of the features listed in Table 25-6. The VC is decreased and does not show a smooth curve, reaching a maximum value. The decreased VC is often accompanied by relatively normal expiratory airflow, increased FEV₁/FVC ratio, and decreased MVV. Supplemental data confirming invalid test results include uneven, slurred, or notched curves on inspection; poor reproducibility on repeated testing; and decreased maximum lung elastic recoil pressure. A valid restrictive pattern differs from a test with poor effort in that it is reproducible and shows smooth expiratory curves on direct examination, increased lung elastic recoil, and a normal or nearly normal MVV.

“Nonspecific” Pattern

In a study of 80,929 pulmonary function test results, what has been termed the “nonspecific” pattern was described, which consists of a reduced FEV₁ and/or FVC with a normal FEV₁/FVC and normal TLC. This pattern was identified in 7702 subjects (or ≈10%).²⁹⁸ The ATS/European Respiratory Society consensus statement considers this pattern as representing incomplete inhalation and/or exhalation and ultimately classified this pattern as obstructive.²⁹⁹ The original study was followed up with a longitudinal study of 1284 subjects who had one or more pulmonary function tests performed 6 months or more after initial testing, with a median follow-up of 3 years. The authors used a multivariate, multinomial logistic regression model to study the association between different variables and the final pulmonary function pattern. Their findings revealed that the nonspecific pattern was reproduced in 64% of subjects. Roughly equal numbers of subjects (≈15%) went on to develop a restrictive or obstructive pattern, whereas 3% normalized and 2% showed a mixed pattern.³⁰⁰ These data highlight the importance of longitudinal follow-up in patients with conflicting pulmonary function patterns.

Role of Obesity

Obesity is common in the United States and contributes to increased risk for death from heart disease and diabetes. It also increases the risk from anesthesia and surgical procedures, especially for procedures involving the upper abdomen and thorax. Obesity also complicates life for

individuals with pulmonary disease because it increases the work of breathing. Obesity also increases the symptoms and adverse physiologic consequences of airway obstruction. Because of the increased extrathoracic mass, these patients are forced to breathe at low lung volumes, where airway diameters are decreased. The increased work of breathing at low lung volumes and reduced airway diameters interacts with the increased work of breathing due to increased extrathoracic mass. These factors are particularly troublesome, especially if the obese patient develops even mild airflow obstruction.³⁰¹ Obesity is also often associated with sleep disorders and impaired regulation of ventilation. In general, obesity limits exercise tolerance, and it makes physical conditioning more difficult to attain and maintain. (For a summary of the effects of mild obesity on lung function, see eTable 25-3).

The increased mass of the chest and abdominal walls and their contents results in decreased outward recoil of the chest wall and increased pressure within the abdomen. Expiratory reserve volume and FRC are decreased, especially when the obese subject is recumbent.³⁰² The single-breath nitrogen washout test results are abnormally increased, and perfusion is increased to poorly ventilated, dependent lung zones at the bases.³⁰³ This results in airway closure, often at lung volumes greater than FRC, with associated arterial hypoxemia.³⁰⁴ DL_{CO} is often increased in mild to moderate obesity and is associated with an increased red blood cell mass, cardiac output, and central blood volume. On the other hand, in morbid obesity DL_{CO} is usually decreased secondary to airway closure and atelectasis.³⁰⁵ Ventilatory response to carbon dioxide is often reduced; in some subjects the ventilatory responses to both hypoxia and hypercapnia are abnormal.³⁰⁶ Fatty infiltration of respiratory muscles may decrease maximum respiratory pressures, aggravate the abnormal lung volumes, and inhibit the capacity to maintain the increased work of breathing. As mentioned, obese patients who also have asthma or other forms of obstructive ventilatory defects usually have increased symptoms relative to the severity of the airway obstruction because they are forced to breathe at low lung volumes, where airflow resistance is increased.^{306a}

A large study of almost 1500 adults in the general population who were followed for 8 years revealed that the detrimental effect of weight gain might be reversible because lung function improved in all those who lost weight. Obese patients with ventilatory impairment should therefore be encouraged to lose weight.^{307,308,308a}

Aging Lung

Aging is associated with a decrease in lung elastic recoil pressure at TLC and at all lower lung volumes. Colebatch and coworkers³⁰⁹ showed that the index of curvature in the exponential expression of lung elastic recoil (see “Lung Elastic Recoil” section) increases with age. They concluded that this change was related to increased alveolar size. These findings were confirmed by Knudson and Kaltenborn,³¹⁰ and morphologic studies have confirmed the increased alveolar dimensions. The effect of age on airflow rates depends on whether the data are based on cross-sectional studies or longitudinal studies. Burrows and associates³¹¹ found that the progressive decline in FVC and FEV₁ did not begin until the middle 30s, and that the subsequent

eTable 25-3 Effects of Mild Obesity on Lung Function

decline in FEV_1/FVC was linear with age, independent of FVC, similar in men and women, and much less severe than that described in cross-sectional studies. Gelb and Zamel³¹² reported decreased maximal flows but no change in lung elastic recoil pressure or RAW with age, suggesting that airway collapsibility increased with age. More recently, Babb and Rodarte³¹³ confirmed work by Janssens and coworkers,³¹⁴ indicating that decreases in maximal expiratory airflow and in the minimum pressure needed to generate maximal flow in older subjects were due to decreased static lung elastic recoil compared with that in younger subjects. VC decreases with age, whereas RV and closing volume increase with age,³¹⁵ suggesting that lung emptying is limited with increasing age because of airway closure (see earlier discussion).³¹⁶ MVV decreases approximately 30% between 30 and 70 years of age, probably as a consequence of decreased maximal respiratory pressures, decreased distensibility of the total respiratory system, decreased lung elastic recoil, and impaired coordination of the respiratory muscles.

The slope of the alveolar plateau measured in the single-breath nitrogen washout test increases with age. Although arterial PCO_2 does not change with age, arterial PO_2 declines³¹⁶ and the $(A-a)PCO_2$ widens with age.³¹⁷ These changes probably reflect the increase in closing volume relative to expiratory reserve volume. Georges and coworkers³¹⁸ reported that DL_{CO} decreases because membrane diffusing capacity decreases after 40 years of age; pulmonary capillary blood volume is maintained until the seventh decade and then decreases rapidly. The accelerated decline in DL_{CO} over the age of 40 years was confirmed by Viegi and colleagues.³¹⁹ These changes appear to be consistent with the results of morphologic studies of the aging lung, which show a decrease in the surface area of the alveoli and the capillary bed.

Abnormal Respiratory Muscle Function

Increasing attention has been focused on the evaluation of respiratory muscles to detect abnormal function as a cause of unexplained dyspnea or respiratory failure. Inspiratory muscles may become fatigued and fail to contract adequately despite effective neural stimulation. If not detected and treated adequately, respiratory failure may result. This problem may develop in patients with obstructive or restrictive ventilatory defects, neuromuscular disorders such as myasthenia gravis, cardiogenic shock, or sepsis.²⁸⁴

Inspiratory Muscle Function Tests. Inspiratory muscle function may be tested clinically by measuring muscle strength or endurance. Common measurements include maximally negative airway pressure, *maximum transdiaphragmatic pressure* ($P_{di,max}$), MVV, diaphragmatic EMG, and fluoroscopy.

For more details about these measurements of muscle function, please see the online version of the chapter.

Events Precipitating Respiratory Failure. Any one of three events may precipitate respiratory failure: increased work of breathing, decreased energy supply, and decreased muscular efficiency.

INCREASED WORK OF BREATHING. Higher airflow resistance or greater elastic recoil of lung or chest wall, or both, may

increase the work of breathing and the energy required of the respiratory muscles.

DECREASED ENERGY SUPPLY. Reduction in the supply of vital metabolic substrates may limit the efficiency of respiratory muscles under certain circumstances. Reduction in cardiac output, arterial oxygen content, or extraction of oxygen from the blood (or a combination of these factors) may impair aerobic metabolism and compromise respiratory muscle function. Decreased oxygen delivery may be critically important under conditions that increase respiratory work. Oxygen consumption by respiratory muscles may rise 25-fold above baseline under conditions of high ventilatory requirement and increased RAW, and it may exceed supply. Forceful muscle contraction alone impedes blood flow to respiratory muscles in animals breathing against increased respiratory workloads. Other variables related to metabolism (e.g., hypercapnia, malnutrition, acidosis, electrolyte disorders) may also limit endurance.

DECREASED MUSCULAR EFFICIENCY. The number and distribution of fiber types determine inspiratory reserve. Disease processes and inactivity may alter the number and relative proportions of fibers in the diaphragm. Under certain conditions, changes in the distribution of fiber types or the loss of fibers may play an important role in the development or maintenance of respiratory failure. For example, atrophy of respiratory muscles is a potentially important problem in patients undergoing long-term mechanical ventilation.³²⁶

Muscular efficiency depends on mechanical factors as well as on structure.²⁸⁴ The position and configuration of the diaphragm at the beginning of inspiration determines the resting length of the muscle fibers. As FRC increases, the contour of the diaphragm flattens, and muscle fibers are not stretched to their optimal length. Acute hyperinflation (as in asthma) may cause a mechanical disadvantage of the diaphragm by shortening muscle fibers. In addition to changing muscle fiber length, hyperinflation also causes a mechanical disadvantage by changing the shape of the diaphragm. The $P_{di,max}$ is determined by the radius of curvature of the diaphragm at any value of muscle tension (Laplace's law). Thus, increasing the radius of curvature of the diaphragm (i.e., flattening the diaphragm) greatly reduces its capacity to develop P_{di} and to change lung volume.

Although abdominal muscles are usually regarded as expiratory, abdominal muscle tone may be needed to maintain the mechanical advantage of the diaphragm. Thus flaccidity of abdominal muscles contributes to the inefficient ventilation seen in paraplegic patients, especially when these patients are in the upright position.

VC is a useful test of respiratory muscle weakness because normally a small fraction of the muscle strength is required to inflate the lung. Furthermore, the curvilinear relationship between pressure and volume means that a greater loss of muscle strength (pressure) is required to produce a loss of volume; for example, a 50% decrease in MIP is associated with only a 15% decrease in VC. Although MIP may be reduced markedly before lung volume decreases, most patients with respiratory muscle weakness have decreased VC and decreased lung compliance. The latter finding is thought to result from atelectasis, which may be detectable in chest radiographs. FRC, inspiratory capacity, expiratory reserve volume, and TLC may also be decreased in

MAXIMALLY NEGATIVE AIRWAY PRESSURE. The maximally negative airway pressure measures the maximally negative airway pressure generated by an inspiratory effort against an occluded airway. In this test the subject inspires maximally from RV against an obstructed mouthpiece with a small leak (1 mm in diameter) to prevent closure of the glottis or development of pressure above the glottis by the muscles of the cheeks. A plateau pressure should be maintained for at least 1 second. Reproducible maximal values are difficult to obtain; the coefficient of variation is about 9% for duplicate tests for the *maximal inspiratory pressure* (MIP) and the *maximal expiratory pressure* (MEP).³²⁰

MAXIMUM TRANSDIAPHRAGMATIC PRESSURE. $P_{di_{max}}$ is measured during the same maneuver by determining the difference between intragastric and esophageal pressures. These pressures should be measured at RV because maximally negative airway pressure is reduced at larger lung volumes. Conversely, MEPs are greatest at TLC. Because it is difficult to obtain cooperation from patients to exhale to RV, MIP, MEP, and $P_{di_{max}}$ are often measured at FRC (which probably accounts in part for the reported variability). Healthy persons can sustain respiratory patterns requiring 40% of $P_{di_{max}}$ for long periods without fatigue. When a patient must increase the $P_{di}/P_{di_{max}}$ ratio to overcome a resistive load, endurance decreases in proportion to the resistive load (eFig. 25-27). Normal subjects can inspire with varying degrees of diaphragm and rib cage contraction. Thus $P_{di_{max}}$ may be decreased because of marked recruitment of the rib cage during the test. The range reported is accordingly large: 18 to 137 cm H₂O. Training results in improved coordination and reproducible values with a coefficient of variation of 19%.³²¹

Similowski and colleagues³²² have reported the use of *cervical magnetic stimulation* (CMS) as a method of phrenic nerve stimulation. They reported the results of comparisons of stimulated Pdi with the maximal Pdi obtained during the static combined expulsive-Mueller maneuver ($P_{di_{max}}$) and with the Pdi generated during a sniff test. Their results were comparable to those obtained in other studies using transcutaneous phrenic stimulation. They were highly reproducible in all the subjects. EMG data provided evidence of bilateral maximal stimulation. CMS is a nonspecific method and may stimulate various nervous structures. Co-contraction of neck muscles, including the sternomastoid, was present, but its influence in the CMS-induced Pdi appeared minimal. The method appears to avoid the pain of transcutaneous phrenic stimulation and the potential danger of needle stimulation of the phrenic nerves. However, subsequent studies showed that CMS stimulated many muscles of the upper thoracic cage as well as the

diaphragm. Investigators have used chest wall electrodes to record the diaphragm compound action potential to assess the extent of stimulation of other muscles.³²³

Although initially promising, these studies have demonstrated difficulty in obtaining surface signals of acceptable quality.³²⁴ The variable shape and latency of the action potential induced by magnetic stimulation plus the shorter phrenic nerve conduction times with CMS compared with electrical stimulation indicate that diaphragm EMG after CMS is potentially unreliable, perhaps because chest wall electrodes also record electrical activity from other muscles. As demonstrated by Luo and associates,³²⁵ the method also appears unreliable for the measurement of phrenic nerve conduction time.

MAXIMUM VOLUNTARY VENTILATION. MVV measurements can also be used to assess endurance. Endurance decreases as VE/MVV increases in a pattern similar to that observed with increasing $P_{di}/P_{di_{max}}$ ratio. In the absence of an external resistance, the largest ventilation that can be sustained more than 15 minutes is approximately 60% of the MVV.

DIAPHRAGMATIC ELECTROMYOGRAPHY. This is another technique used to evaluate respiratory muscle strength and endurance. Changes in respiratory muscle electrical activity appear to reflect closely other aspects of muscle contraction. Normally the phrenic nerve stimulates the diaphragm at a mixture of frequencies between 20 and 400 Hz. A graphic display of the EMG signal strength against frequency is called the *power spectrum*. When the EMG is analyzed over two limited frequency ranges (<50 Hz and >150 Hz), the power spectrum shifts to the low-frequency range as the diaphragm fatigues. This change precedes failure of contraction, and it therefore may be useful to predict decompensation of the respiratory muscles. Phrenic nerve conduction time may also be used to assess diaphragmatic paralysis or weakness. With recording electrodes placed over the rib cage above the diaphragm, the phrenic nerve is stimulated in the neck. Normal conduction time is 7.7 ± 0.8 msec.

FLUOROSCOPY. Fluoroscopy may be used to evaluate diaphragmatic function. Decreased excursion should be evaluated with a lateral view using the "sniff test." Decreased excursion alone is nonspecific, but decreased excursion associated with paradoxical motion during the sniff test is very specific. False-negative findings may result during spontaneous breathing because of contraction of abdominal muscles during exhalation, which produces downward motion of the diaphragm when the abdominal muscles relax at the beginning of inspiration. False-positive results may be produced by paradoxical motion limited to the anterior portion of the diaphragm.

association with decreased lung elastic recoil, suggestive of decreased outward recoil of the chest wall.

According to Rochester and Esau,³²⁷ substantial respiratory muscle strength can be lost without a change in spirometric values or ABG levels. There is a moderate decrease in MVV and increased RV, and MIP and MEP may be 50% of predicted normal. In advanced chronic disease, patients still may not have symptoms because they are not exercising. When patients reach the stage of poor cough, scoliosis, absent gag reflex, and MIP and MEP less than 50% of predicted normal, MVV is decreased more and RV enlarges further. Overt respiratory failure may develop abruptly, so it is important to follow these patients serially with VC and MIP/MEP studies.

Lung Transplantation

Lung transplantation can improve the quality of life and the capacity to exercise in patients with end-stage emphysema or interstitial lung disease, but it is not clear if it prolongs life.^{328,328a} In single-lung transplantation for emphysema, the radius of curvature of the dome of the diaphragm and the zone of apposition of the diaphragm with the chest wall on the side of the graft return to normal. The surface area of the dome also becomes smaller on the side of the graft compared with controls.³²⁹ This effect results from mediastinal displacement toward the graft, due to the lesser lung elastic recoil of the native (emphysematous) lung and greater lung elastic recoil of the graft. The disparity in elastic recoil may be increased if the graft is infected or undergoes rejection. It has also been suggested that mediastinal shift toward the graft may reflect dynamic hyperinflation of the native lung. Such dynamic hyperinflation seems unlikely because single-lung transplants do not show flow limitation during tidal breathing except during maximal exercise.³³⁰ Mediastinal displacement is usually counterbalanced by equal expansion of the rib cage on the side of the graft. Compensatory expansion of the rib cage on the graft side is not always sufficient to accommodate expansion of the contralateral hyperinflated lung. In rare cases the mediastinal shift can compromise function of the graft. This risk depends on the severity of obstruction and air trapping preoperatively.

When patients with a single-lung transplant inhale to TLC, they attain only 78% of the volume of matched controls. The smaller volume is due to mediastinal shift, mismatch in sizing the graft relative to the native lung and rib cage, and reduced capacity of inspiratory muscles to generate required pressures. Smaller inspiratory pressures may result from shorter operating length of the inspiratory muscles, steroid myopathy, or the respiratory myopathy caused by the vehicle used with cyclosporine.³³¹

Transplantation of two lungs results in a normal TLC in patients with chronic hyperinflation (FRC about 1 L above predicted levels).³³² Electrical stimulation and sniff-induced Pdi are not affected by single-lung transplantation. However, after bilateral lung transplantation, increased resting length of muscle fibers and normalization of the radius of curvature of the diaphragm lead to improved sniff pressure and normal MIP.³³³ It is still uncertain why MEP is only 70% of normal, even after double-lung transplantation. The fact that weakness of expiratory respiratory muscles and ankle dorsiflexors is equivalent suggests that these muscles may

be vulnerable to a factor that does not affect the diaphragm, perhaps because the diaphragm is active continuously.³³⁴ Inspiratory muscle endurance does not change after single-lung or double-lung transplantation.

A major problem, well recognized by transplant surgeons, is the need to obtain a proper fit of the donor graft within the chest cavity of the recipient. As suggested by Fessler and Permutt (see earlier discussion of lung volume resection surgery), a mismatch in size of the single-lung (or double-lung) graft and the size of the surrounding chest, as reflected by RV/TLC, has a profound effect on pulmonary function. If the donor graft is too large for the chest cavity, regardless of how healthy the graft is, the respiratory muscles of the recipient are unable to generate sufficient pressures to improve expiratory airflow and reduce hyperinflation and air trapping.

In patients with a single-lung or double-lung transplant, maximal exercise capacity is about half normal. This is not the result of ventilatory limitation, as it is in COPD patients without transplantation. The ventilatory reserve during maximal exercise is similar in transplant patients and matched controls. Evidence suggests that exercise limitation after transplantation results from decreased strength and endurance of locomotor muscles. Compared with healthy controls, transplant patients have shorter time to exhaustion, greater acidosis in quadriceps during knee-extension exercise, decreased type I fibers, and markedly decreased mitochondrial oxidative capacity.^{335,336}

AIRLINE TRAVEL

The increase in air travel makes it important for family physicians and specialists to be able to advise patients concerning the medical risks involved. Cardiovascular and pulmonary problems are the most common reasons for excluding air travel. Hypoxia in the aircraft, despite pressurization to the equivalent of 6000 to 8000 feet altitude, may be dangerous for patients with unstable angina, severe congestive heart failure, or chronic airway obstruction.³³⁷ Patients with severe lung disease associated with arterial oxygen desaturation should be evaluated at sea level for the risk for hypoxia during air travel or during travel to high altitude. Measurement of arterial PO₂ at ground level (as close to departure as possible) is a good predictor of tolerance to altitude, because hypoxia is the most important stress for patients with pulmonary disease at high altitude. If arterial PO₂ at altitude is 55 mm Hg or greater with a saturation of 85% to 90% or greater, the patient should tolerate air travel reasonably well.

Using altitude *simulation* (using low-oxygen mixtures or hypobaric chambers), it is possible to assess symptoms, tolerance to exercise, amount of supplemental oxygen required, and effects of controlled hypoxia on associated hematologic, cardiac, and neurologic disorders. Such information cannot be obtained from the prediction of altitude arterial PO₂ alone. Furthermore, the equations for estimation of hypoxia at altitude are relatively population-specific (i.e., limited to COPD patients) and only deal with the effects of altitude on arterial oxygenation.

Thus, although predictions may be useful in patients with COPD, they may be misleading in patients with other conditions. For example, in children with cystic fibrosis,

The arterial PO_2 at altitude in patients with chronic airflow obstruction may be estimated from the following equation³³⁸:

$$\text{PaO}_2 = 22.8 - 2.74(\text{altitude}) + 0.68(\text{PaO}_2 \text{ at sea level}) \quad (50)$$

where altitude is given in thousands of feet. The use of FEV_1 may enhance the accuracy of prediction of the arterial PO_2 at 8000 feet in patients with chronic airflow obstruction³³⁹:

$$\text{PaO}_2 = 0.453(\text{PaO}_2 \text{ at sea level}) + 0.386(\text{FEV}_1) + 2.440 \quad (51)$$

where FEV_1 is given as percentage of predicted normal.

As suggested by Gong and associates,³³⁸ while the patient breathes hypoxic gas mixtures equivalent to the atmospheric oxygen at 8000 feet (15.1% oxygen, representing “worst case” cabin pressurization excluding accidental depressurization), measurements can be made of pulse oximetry or ABG levels combined with electrocardiographic monitoring at rest and during exercise. Although measurements of ABGs may be used to predict the likely oxygenation of pulmonary patients at altitude, more objective information may be obtained from a hypoxia-altitude

simulation test. Berg and associates³⁴⁰ approached altitude simulation directly and studied patients with COPD [FEV_1 0.97 L ($\pm 31.3\%$)] in a hypobaric chamber to simulate a commercial jet aircraft cabin at the equivalent of 8000 feet altitude. When breathing supplemental oxygen by nasal cannula at 4 L/min, the mean arterial PO_2 increased from 47.4 ± 6.3 mm Hg to 82.3 ± 14 mm Hg ($n = 18$). Supplementation of oxygen by 24% Venturi mask caused arterial PO_2 at 8000 feet to increase by 12.7 ± 3.8 mm Hg; a 28% Venturi mask caused arterial PO_2 at 8000 feet to increase by 19.7 ± 8.2 mm Hg. Compared with ground level, oxygen at 4 L/min (by nasal cannula) increased mean arterial PO_2 by 9.9 ± 12.6 mm Hg; 24% and 28% Venturi masks did not cause mean arterial PO_2 to increase above ground-level values. These changes could be evaluated accurately using a transmittance ear oximeter and less accurately using a reusable digital pulse oximeter.³⁴¹

These results suggest that altitude simulation studies may be more accurate in assessing hypoxemia and the effect of treatment with supplemental oxygen than predictions of altitude arterial PO_2 based on studies at ground level.

simple spirometry and baseline arterial PO_2 may underestimate the individual response to air travel or altitude.³⁴² In a study of 17 patients with restrictive ventilatory defects, Christensen and colleagues³⁴³ reported the effect of simulated air travel in a hypobaric chamber on ABGs, blood pressure, and cardiac frequency during rest and mild exercise, and the response to supplementary oxygen. They found that resting arterial PO_2 was much lower than predicted by an equation, and that arterial PO_2 fell further with light exercise. Thus, for patients with diseases other than COPD, it is probably prudent to use some form of altitude simulation to estimate the possible physiologic and clinical effects of altitude or air travel on patients with pulmonary disease.³⁴⁴⁻³⁴⁶

INFECTION CONTROL AND SAFETY

When patients with communicable infectious diseases are referred for pulmonary function tests, they always present a potential risk for transmission of infectious diseases to the technical and administrative staff of the laboratory, as well as to other patients who may be in the laboratory for studies at the same time. Pulmonary laboratory directors are familiar with the risk for spreading tuberculosis by aerosols produced by sputum-positive patients. There has also been the more theoretical possibility of transmitting tuberculosis from one patient to another via infected secretions, which may contaminate pulmonary function equipment. The increasing number of immunosuppressed patients in cancer treatment and transplantation programs has raised the possibility of increased risk for transmission of infection to such patients.

Key Points

- There are two main ventilatory patterns measured by pulmonary function tests: obstruction and restriction. Categorization of these patterns is dictated by the lung volumes, both static and forced, as well as the interpretation of the flow-volume loop.
- Because pulmonary function testing is effort dependent, technicians must be trained sufficiently and laboratories must adhere to high standards to obtain the most accurate and reproducible results possible.
- Measurements from spirometry alone can be useful in patients whose main physiologic impairment is airway obstruction. The findings from spirometry can provide clues that concomitant restriction is present; however, for assessment of restriction, lung volumes must be measured.
- In patients with reversible mild airway disease, the results of pulmonary function tests may be normal because the disease is dynamic and patients with mild airflow obstruction may spontaneously return to normal.
- The diffusing capacity measurement is used to determine defects of the alveolar-pulmonary capillary unit. A defect in the diffusing capacity alerts the physician that oxygen transfer, the alveolar-capillary membranes, and/or pulmonary capillaries may not be normal, and further evaluation of the underlying cause of this defect should be pursued.
- Methacholine provocation testing is used to identify whether abnormal airway responsiveness is present. Usually this indicates a diagnosis of asthma, but the clinician must understand that other conditions that involve airway inflammation, such as sarcoidosis, may also show abnormal airway responsiveness.

With the *human immunodeficiency virus* (HIV) epidemic and the recent severe acute respiratory syndrome epidemic and the possible risk for transmission of a lethal virus, this issue has been rigorously reassessed. It is not possible to screen everyone studied in a laboratory for HIV infection or the *acquired immunodeficiency syndrome* (AIDS) before testing. Furthermore, in hospitals in which large numbers of patients with chronic liver disease are evaluated for possible liver transplantation, there is a high prevalence of diverse hepatitis viruses, which are also difficult if not impossible to screen out before pulmonary function testing.

For these reasons, on the advice of the Infectious Disease Control Committee and the AIDS Advisory Committee at University of California, San Francisco, the laboratory with which I am affiliated has adopted a uniform protocol designed to protect all patients and technical staff from possible infectious diseases. When a patient is sent to the laboratory, the administrative assistant responsible for the schedule makes certain the requisition is completed. The requisition is designed to screen for possible HIV, tuberculosis, and other infectious diseases. The administrative assistant also checks for these possibilities with the referring physician when the study is scheduled. When the patient arrives at the laboratory for the study, the technicians check for possible communicable infectious diseases on the requisition, the medical record, and the questionnaire completed by the patient. If this review is negative, studies are

performed. All patients are studied on the same equipment. All studies are performed with the patient breathing through a filter that traps particles as small as 0.2 μm in diameter and does not affect the results of the physiologic tests performed. It is assumed that infectious particles, whether bacterial, fungal, parasitic, or viral, will be carried in respiratory secretions of such a large size that all of them will be trapped by these filters. No infectious diseases have been transmitted from the equipment in this laboratory, a fact that reinforces these assumptions. The fact that the Centers for Disease Control and Prevention has not reported transmission of HIV or hepatitis virus via pulmonary function equipment also reinforces the assumptions.

Because of the expense of effective filters, an alternative and conservative policy might include the following: careful screening of patients before testing; use of disposable mouthpieces that are discarded after single-patient use or rubber mouthpieces that are changed between each patient and cleaned with high-level disinfection procedures; replacing external spirometer tubing between patients, with high-level disinfection and drying of the tubing between each use; replacing nose clips between each patient and discarding used nose clips or cleaning them with high-level disinfection procedures; changing the water in water-sealed spirometers at least monthly; and washing hands thoroughly before and after pulmonary function testing, with appropriate use of gloves when blood samples are to be collected.

eFIGURE IMAGE GALLERY

eFigure 25-1 Relationship between driving pressure (x-axis) and airflow (y-axis) through a series of critical orifices of varying diameters (in mm). Using this family of curves, it is possible to determine the diameter of a critical orifice in a patient with upper airway obstruction. Assuming a driving pressure of 100 cm H₂O, the diameter is given by the curve closest to the maximum flow observed in the flow plateau obtained from the flow-volume loop obtained from the patient. Curves were constructed by using graded external resistances in a normal subject.

eFigure 25-2 Volume (open-type) plethysmograph. In this constant-pressure, variable-volume type of plethysmograph, the subject also breathes through a shutter/pneumotachygraph apparatus, which usually is located outside the plethysmograph itself. The shutter is open for tidal breathing, measurement of airway resistance, and spirometry. It is closed for measurement of thoracic gas volume. In the closed-shutter mode, mouth pressure is measured by a transducer (1) and approximates alveolar pressure with no flow and small volume changes. The pneumotachygraph measures flow via another transducer (2, above the pneumotachygraph). Flow is integrated electronically to obtain volume. Changes in volume of the plethysmograph, reflecting movement of the chest wall, are measured with a spirometer and a linear volume-displacement transducer (LVDT). The spirometer illustrated is a Krogh water-sealed spirometer with good frequency response and very small impedance to gas displacement. A low-resistance pneumotachygraph (flowmeter) with a fast, drift-free integrator may be used instead. Processing is usually performed by computer and permits slow and forced vital capacity maneuvers as well. However, neither approach is routine.

eFigure 25-3 Pressure-volume (or flow) plethysmograph. This type of plethysmograph combines features of the closed and open types. The subject breathes through a shutter/pneumotachygraph apparatus. The shutter is open for tidal breathing, measurement of airway resistance, and spirometry. It is closed for measurement of thoracic gas volume. In the closed position, mouth pressure (alveolar pressure) is measured by a transducer (top). The pneumotachygraph at the mouth (pneumotachygraph 1) measures airflow with another transducer (middle). This airflow at the mouth is integrated to obtain volume inhaled and exhaled at the mouth. Changes in plethysmograph or box volume resulting from movements of the chest wall are measured by a pneumotachygraph in the wall of the plethysmograph (pneumotachygraph 2) with a third transducer (bottom), and this signal is integrated to obtain volume change of the thorax. The signals from all three transducers usually are processed by computer to obtain slow and forced vital capacities as well as resistance and thoracic gas volumes.

eFigure 25-4 Physical principles underlying pressure-volume plethysmography. **A**, The theoretical “true” instantaneous volume event. During this event, plethysmographic pressure increases rapidly and then decays exponentially (**B**). If the plethysmographic pneumotachygraph is linear, the flow signal has a shape similar to that of the pressure transducer (**C**). This flow signal is integrated to obtain volume (**D**), which reaches the same level as the true volume event, but the shape does not conform to the “true” event. The difference is a result of the compression of a large volume of gas in the plethysmograph and is directly proportional to the plethysmograph pressure. Therefore, by adding a portion of the plethysmograph pressure to the integrated plethysmograph flow (**E**), the true volume event is reconstructed accurately: $\Delta V = P_{box} + \int \dot{V}_{box}$. Thus the true volume is obtained by adding the plethysmographic compression volume (P_{box}) and the displacement volume ($\int \dot{V}_{box}$). More precisely, (1) box pressure (P_{box}) is multiplied by a constant (K_{box}), a factor to correct pressure to volume that is proportional to the gas volume in the box (total box volume – patient volume); and (2) P_{box} is also divided by the box flowmeter resistance (R_{box}) to yield box flow (\dot{V}_{box}), and integrated to obtain volume (V_{box}). These two signals are added together to yield the change in lung volume: $\Delta V = P_{box}K_{box} + P_{box}/R_{box} \int \dot{V}_{box}$.

eFigure 25-5 The rectangle represents a closed, constant-volume, variable-pressure whole-body plethysmograph. As described in eFigure 25-4, at end-expiration airflow is zero, thoracic gas volume (V) = functional residual capacity, and alveolar pressure (P_{alv}) = mouth pressure (P_M) = barometric pressure (P_{bar}). When the subject inhales against an occluded shutter in the airway, airflow remains zero, but V increases by ΔV to V' and P_M (= P_{alv}) increases by ΔP ($P + \Delta P$) to equal P' . When P_M is plotted against P_{box} , the slope of the line (α) yields $\Delta V/\Delta P_{alv}$, and $V = \Delta V/\Delta P_{alv} \times P_{bar}$, as indicated in the text. \dot{V} , airflow. (Modified from Comroe JH Jr, Forster RE II, DuBois AB, et al: *The lung: clinical physiology and pulmonary function tests*, ed 2, Chicago, 1962, Year Book.)

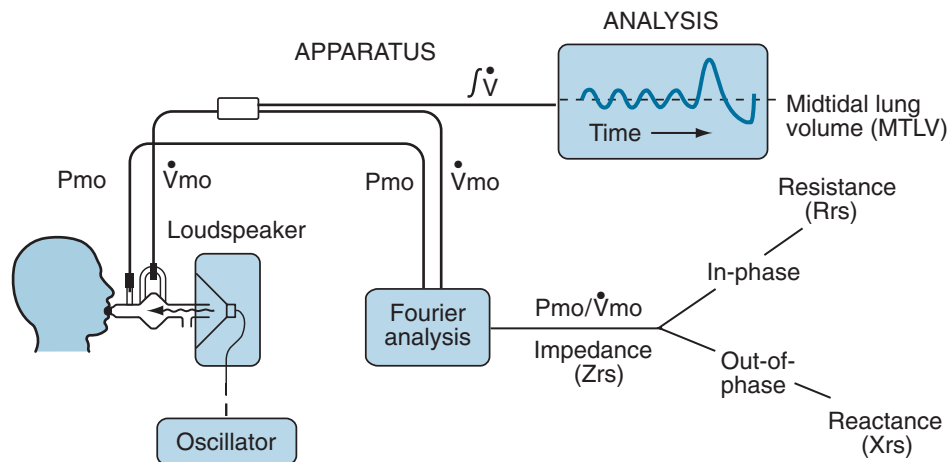

Figure 25-6 Measurement of respiratory resistance by forced oscillation. A loudspeaker may be driven to produce a sinusoidal oscillation at a single frequency, a sequence of sinusoidal oscillations at diverse single frequencies, or a random noise signal. The flow signal is integrated to yield tidal volume or, at the end of the study, inspiratory capacity. The recorded signals for mouth pressure (P_{mo}) and flow (\dot{V}_{mo}) are directed to a Fourier analyzer, and the component of each signal caused by the applied oscillation is differentiated from changes caused by tidal breathing. Impedance (Z_{rs}) is calculated over a wide range of frequencies. The impedance is subdivided into the in-phase and out-of-phase components of the primary signals. The in-phase signal is the resistance of the total respiratory system (R_{rs}), and the out-of-phase signal is the reactance (X_{rs}), sometimes called the imaginary part of the impedance. The reactance is related to the compliance and inertance of the respiratory system (see text). (Modified from Hughes JMB, Pride NB: *Lung function tests*, London, 1999, WB Saunders, p 35.)

Figure 25-7 Schematic drawing illustrating the position of an esophageal balloon in relation to adjacent structures. The balloon is made of latex (wall thickness, 0.06 mm; length, 10 cm; circumference, 3.5 cm). The tubing is polyethylene (inner diameter, 0.14 cm; outer diameter, 0.19 cm) with holes placed in a spiral arrangement in the portion inside the balloon. The balloon is filled with 0.2 to 0.4 mL of air and positioned in the lower third of the esophagus. Intraesophageal pressure recorded from the catheter within the balloon is affected by the following factors in addition to static transpulmonary pressure: retractile pressure of balloon wall (1), pressure caused by resting esophageal tension (2), and pressure caused by mediastinal structures (3), including pulsations of the heart (4).

Figure 25-8 Measurement of expiratory flow limitation by negative expiratory pressure (NEP) method. *Left*, The experimental setup. The subject breathes tidally through a pneumotachygraph that records flow (\dot{V}), which is integrated to yield tidal volume (V_T). After recording baseline V_T , a negative expiratory pressure of -5 cm H_2O is applied to the subsequent V_T , in which the pressure at the airway opening (P_{ao}) is reduced by 5 cm H_2O . *Right and center*, Examples of tidal flow-volume curves. Both results were obtained during exercise. In the normal subject (*center*), expiratory flow increases, but except for a transient spike of flow, there is no change in flow in a patient with COPD (*right*). Note that the flow and volume scales are different in the two panels, as are the shapes of the curve in the normal individual (rectangular) and in the COPD patient (*right*). The change in volume during exercise is referred to as the functional residual capacity (FRC) at rest. Note the decrease in volume in the normal lung and the increase in volume in the COPD lung during exercise. The *dashed lines* indicate the full maximal flow-volume curves in both subjects. There is a large reserve of expiratory flow in the normal subject, whereas tidal expiratory flow exceeds the full flow-volume envelope at the same volume in the COPD patient. MEFV, maximal expiratory flow-volume. (Modified from Koulouris NG, Dimopoulou I, Volta P, et al: Detection of expiratory flow limitation during exercise in COPD patients. *J Appl Physiol* 82:723–731, 1997.)

Figure 25-9 Relationship between nitrogen (N_2) concentrations in different regions of lung (top) and the single-breath N_2 washout test of distribution of ventilation (bottom). *Top*, Schematic illustration of a ventilatory unit near the lung apex (*dark blue*) and a ventilatory unit near the base (*light blue*) subtended by a common airway. The intensity of color reflects the end-inspiratory concentration of the resident gas (N_2) at the end of a single maximal inspiration of pure oxygen (O_2) (at total lung capacity [TLC]). The differences in N_2 concentration in each unit result from the effect of differences in regional residual volume (RV) and the distribution of inspired gas (see text). *Bottom*, At the start of exhalation, the gas (pure oxygen) in the conducting airway empties first, and 0% N_2 is recorded (phase I). As exhalation continues, gas from both ventilatory units mixes in the airway, and the N_2 concentration increases rapidly (phase II). With continued exhalation, mixed alveolar gas is recorded by the N_2 analyzer (phase III). Finally, dependent airways at the base of the lungs close near RV (closing volume), and exhalation continues from the apical ventilatory unit of the lung only, which contains a higher N_2 concentration than the basal unit (phase IV).

Figure 25-10 Face-on views of freeze-dried, stained alveolar walls (200- μ m-thick section) showing the distribution of the pulmonary capillary bed in anesthetized cats. A, Zone I lobe. B, Zone II lobe. C, Zone III lobe. Morphometric analysis showed that 21% of the alveolar walls were occupied by red blood cells in zone I lobes, 43% in zone II lobes, and 61% in zone III lobes. Independent changes in pulmonary arterial or venous pressure were associated with changes in the pulmonary capillary blood volume over a threefold range. (From Vriem CE, Staub NC: Pulmonary vascular pressures and capillary blood volume changes in anesthetized cats. *J Appl Physiol* 36:275–279, 1974.)

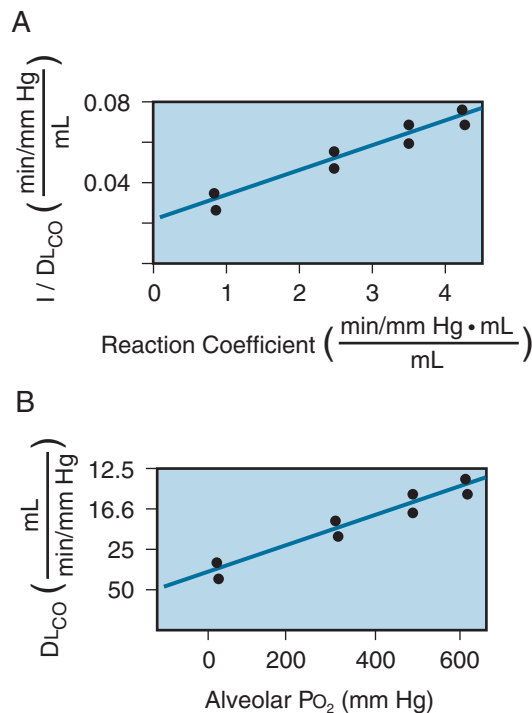

Figure 25-11 Subdivisions of the DL_{CO} . Experimental values of the diffusing capacity for carbon monoxide (DL_{CO}) obtained at different alveolar PO_2 values (x-axis in **B**) can be analyzed mathematically to obtain the subdivisions of total DL_{CO} : the diffusing capacity of the membrane (DM) and pulmonary capillary blood volume (VC). As the alveolar PO_2 was increased from 40 mm Hg to 600 mm Hg, the duplicate measurements of DL_{CO} decreased from approximately 45 to 15 mL/min per mm Hg. Changing alveolar PO_2 changes the reaction coefficient (θ), reflecting the change in hemoglobin affinity for carbon monoxide. The reaction coefficient is plotted against $1/DL_{CO}$ in **A**. There is a linear relationship between $1/DL_{CO}$ and $1/\theta$ such that $1/DL_{CO} = 1/\theta VC + 1/DM$. Under these conditions, DM is derived from the value of the y-intercept and VC from the slope of the line.

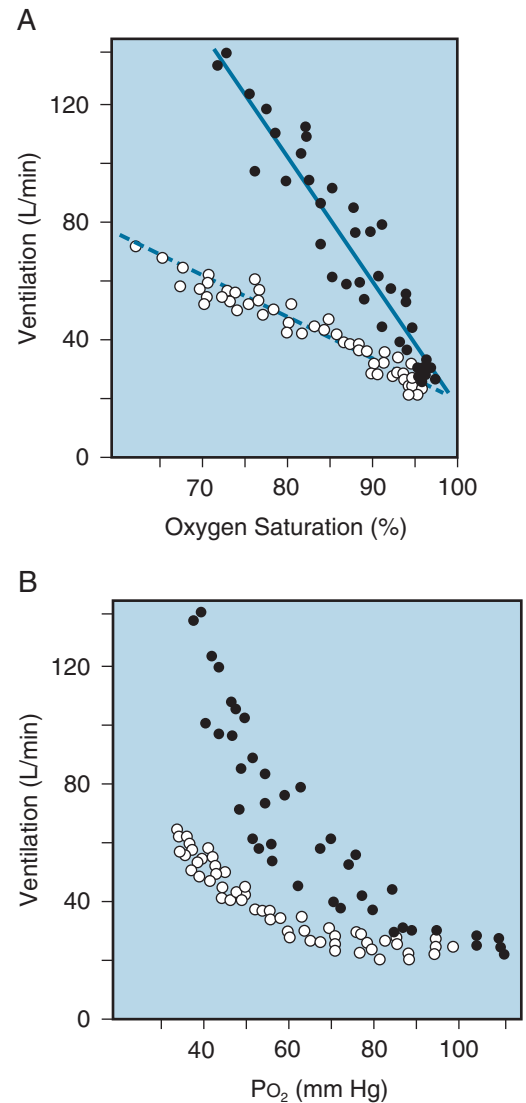

Figure 25-12 Correlation between diffusing capacity for carbon monoxide (DL_{CO}) and emphysema grade. *Top*, The single-breath DL_{CO} , expressed as the percentage of predicted normal, is displayed on the ordinate. Emphysema grade is displayed on the abscissa and was determined by the panel grading method on lung tissue resected from these patients within 1 week of pulmonary function testing. The *solid line* is the line of best fit ($r = -0.73$), the *outer dashed lines* show the 95% confidence limits for the points, and the *inner dashed lines* show the 95% confidence limits for the line. The single-breath DL_{CO} correlates with the presence and amount of emphysema except when emphysema is mild (grades 0 to 30); when single-breath DL_{CO} was plotted against emphysema for patients with minimal disease (grades 0 to 30), there was no significant correlation. *Bottom*, The intrabreath DL_{CO} , expressed as the log of the percentage of predicted normal at 50% exhaled vital capacity, is displayed on the ordinate. Emphysema grade is displayed on the abscissa and was determined by the panel grading method on lung tissue resected from these patients within 1 week of pulmonary function testing. The *solid line* is the line of best fit ($r = -0.77$), the *outer dashed lines* show the 95% confidence limits for the points, and the *inner dashed lines* show the 95% confidence limits for the line. Thus the intrabreath DL_{CO} correlates with the presence and amount of emphysema even when emphysema is mild (grades 0 to 30) and cannot be detected or quantified by the single-breath method.

eFigure 25-13 Comparison of rebreathing and steady-state hypercapnic response curves. Response lines defined by the steady-state method (solid symbols) and by the rebreathing method (open symbols) are shown for two experiments on the same subject. In one experiment, the steady-state points were defined by inhalation of each of four carbon dioxide mixtures for 20 minutes without intervening periods of air breathing. In the other experiment, the steady-state points were defined by inhalation of each carbon dioxide mixture for 30 minutes, with an intervening rest period of 30 minutes. The figure illustrates a difference in position of the response lines due to a smaller PCO_2 gradient between arterial blood and chemoreceptor tissue during the rebreathing method. The close agreement in slope implies that the ratio of change in end-tidal PCO_2 to change in chemoreceptor PCO_2 is the same in the two methods. (Modified from Read DJC: A clinical method for assessing the ventilatory response to carbon dioxide. *Australas Ann Med* 16:20–32, 1967.)

eFigure 25-14 Hypoxic response curves, representing pooled results of four studies in two subjects. **A**, Ventilation is plotted against oxygen saturation, producing linear responses. **B**, The more traditional hyperbolic relationship is obtained by plotting ventilation against alveolar PO_2 . (Modified from Rebuck AS, Campbell EJM: A clinical method for assessing the ventilatory response to hypoxia. *Am Rev Respir Dis* 109:345–350, 1974.)

eFigure 25-15 Inspiratory occlusion pressure at 100 msec (0.1 second) in response to hypercapnia. Each curve is the mean regression of mouth pressure at 0.1 second against PCO_2 for one subject. Inspiratory occlusion pressure may be used to measure the output of the respiratory center in response not only to hypercapnia, but also to hypoxia, exercise, and other factors. (Modified from Whitelaw WA, Derenne J, Milic-Emili J: Occlusion pressure as a measure of respiratory center output in conscious man. *Respir Physiol* 23:181–199, 1975.)

eFigure 25-16 Assessment of regional lung function using xenon-133 (^{133}Xe). *Top*, After injection, the initial peak reflects the regional blood flow (\dot{Q}_c); the isotope then passes into the gas phase, in which the clearance during normal breathing reflects the ventilation of lung tissue that is perfused. A slow washout indicates a low ventilation-perfusion ratio (\dot{V}_A/\dot{Q}_c). *Bottom*, During rebreathing, the plateau count rate when mixing is complete reflects the volume of lung gas in the field of counting. The slopes of the wash-in and washout curves indicate the ventilation per unit volume. (Modified from Cotes JE: *Lung function*, ed 4, Oxford, 1979, Blackwell Scientific.)

eFigure 25-17 Distribution of ventilation-perfusion ratios in a normal person. *Top*, The retention (arterial/venous, *solid line*) and excretion (expired/venous, *dashed line*) data points together with the curves for a homogeneous lung. *Bottom*, Continuous distribution of ventilation-perfusion ratios as found in a semirecumbent young (22-year-old) normal subject by means of the inert gas elimination method. Note the narrow dispersion and the absence of shunt. The *dashed line* indicates ventilation, and the *solid line* indicates blood flow. SF, sulfur hexafluoride. (Modified from West JB: *Ventilation/blood flow and gas exchange*, ed 3, Oxford, 1977, Blackwell Scientific.)

eFigure 25-18 Distribution of ventilation-perfusion ratios in a COPD patient. *Top*, Retention and excretion-solubility curves. *Black lines* indicate data from the patient; *blue lines* indicate data from the normal subject depicted in eFigure 25-17. *Bottom*, Continuous distribution of ventilation-perfusion ratios in a 60-year-old patient with chronic airway obstruction, predominantly emphysema. The *dashed line* indicates ventilation and the *solid line* indicates blood flow. Note the broad bimodal distribution with the large amount of ventilation going to lung units with very high ventilation-perfusion ratios. (Modified from West JB: *Ventilation/blood flow and gas exchange*, ed 3, Oxford, 1977, Blackwell Scientific.)

eFigure 25-19 The structure of a pH electrode, which comprises two cells. The measurement half-cell consists of a fine capillary tube of pH-sensitive glass separating the introduced sample of 25 μ L from the buffered solution and a silver/silver chloride (Ag/AgCl) electrode to conduct the generated potential difference to the electronic circuitry. The reference half-cell usually contains a calomel (mercury/mercurous chloride) electrode in an electrolyte solution to provide a constant reference voltage and is connected to the measurement half-cell by a contact bridge to complete the circuit. Both cells are enclosed in a sealed jacket and maintained at a constant temperature. KCl, potassium chloride.

eFigure 25-20 The structure of a carbon dioxide electrode. This electrode uses the combination of the relationship between PCO_2 and pH in a buffered solution and the design of a pH electrode. The sample is separated from a buffer solution by a membrane permeable to carbon dioxide. The carbon dioxide molecules diffuse through the membrane, altering the concentration of carbonic acid, and therefore the hydrogen ion concentration in the buffered solution. The change in pH is read by a pH meter with output scaled in terms of PCO_2 .

eFigure 25-21 The structure of an oxygen electrode. This electrode consists of platinum and silver electrodes placed in potassium chloride solutions, a polarizing voltage of 0.5 to 0.6 volts, and an electrolyte bridge to complete the circuit. Oxidation at the silver (Ag) electrode secondary to silver reacting with chloride ions to form silver chloride (AgCl) produces electrons that are consumed at the platinum electrode by reduction of oxygen. The flow of electrons (the current) is thus proportional to the concentration of oxygen at the platinum electrode.

eFigure 25-22 Factors influencing detection by pulse oximetry of light absorption through a pulsatile vascular bed. Solid circles represent light absorption by hemoglobin in arterial blood and by the pulse of arterial blood; open circles represent light absorption by hemoglobin in venous blood; shaded zone represents absorption by tissue that absorbs incident light. d , distance through tissue that absorbs incident light.

eFigure 25-23 Absorption spectrum of reduced hemoglobin (Hb) and oxyhemoglobin (HbO₂). Readings are made at 660 nm (red) and 940 nm (infrared) wavelengths.

eFigure 25-24 Normal capnogram. During inspiration, PCO_2 is zero. At the start of exhalation, PCO_2 remains zero as gas from the anatomic dead space leaves the airway (comparable to phase I in the single-breath nitrogen washout test). Next, PCO_2 rises rapidly as alveolar gas mixes with gas from the dead space (comparable to phase II in the single-breath nitrogen washout test), and then the PCO_2 level stabilizes as gas from the dead space decreases and all the gas comes from alveoli containing carbon dioxide. The PCO_2 at the end of the “alveolar plateau” is called the end-tidal PCO_2 (comparable to phase III in the single-breath nitrogen washout test).

eFigure 25-25 Abnormal capnogram. The sudden decrease in end-tidal PCO_2 suggests a life-threatening situation in which the capnograph no longer detects carbon dioxide in the exhaled gas. This capnogram suggests the possibility of esophageal intubation, obstructed endotracheal tube, disconnected airway, or ventilator malfunction; these possibilities must be excluded before it can be assumed that the capnograph is malfunctioning.

eFigure 25-26 Abnormal capnogram with an exponential decrease in end-tidal PCO_2 . Note the progressively more sloping alveolar plateau, reflecting not only abnormal distribution of ventilation but also uneven perfusion relative to ventilation. This pattern suggests a potential life-threatening situation such as cardiac arrest, severe pulmonary hypoperfusion, or pulmonary embolism, as discussed in the text.

eFigure 25-27 Diaphragmatic endurance in two patients in normal and hypoxic conditions. The relationship between endurance and transdiaphragmatic pressure (Pdi) is expressed as a percentage of maximal transdiaphragmatic pressure (Pdi_{max}). Data from two patients breathing normal and hypoxic air are shown. Added resistance leads to an increased $\text{Pdi}/\text{Pdi}_{\text{max}}$ ratio and increases the work of breathing. As the $\text{Pdi}/\text{Pdi}_{\text{max}}$ ratio increases, endurance rapidly decreases. This effect is more pronounced when the respiratory muscles are hypoxic. (Modified from Roussos CS, Macklem PT: Diaphragmatic fatigue in man. *J Appl Physiol* 43:189–197, 1977.)

Contraindications to Cpet
Conducting Exercise Tests

Interpreting Cardiopulmonary Exercise Tests

Alternative Methods of Assessing Exercise Performance

INTRODUCTION

Sustained exercise requires tight integration of multiple physiologic systems including the cardiac, neuromuscular, and respiratory systems. Diseases affecting any of these systems can manifest as dyspnea or exercise limitation. In addition to other modalities commonly used in the assessment of patients with these complaints, *cardiopulmonary exercise testing* (CPET) provides a systematic means to assess exercise responses, unravel the different interacting components, and understand which system is contributing the most to the perceived limitation. Beyond this primary role, CPET has other important uses including (1) quantifying maximal exercise capacity and generating data that can be used to assess functional limitation, (2) prescribing appropriate rehabilitation and training regimens, and (3) guiding clinical decisions about fitness for planned procedures.

The goals of this chapter are to describe the application of CPET in clinical practice and assist the reader in understanding who would benefit from CPET and how it can be used to evaluate dyspnea and exercise limitation. Because CPET interpretation requires a solid understanding of the physiologic responses to exercise, the chapter begins with a review of exercise physiology that sets the foundation for the balance of the chapter. The review includes exercise responses in normal individuals and those with various forms of cardiopulmonary disease, including heart failure, *chronic obstructive pulmonary disease* (COPD), pulmonary vascular disease, *interstitial lung diseases* (ILDs), and adult congenital heart disease. The chapter then describes the primary indications and contraindications of CPET, reviews the various options for conducting exercise tests, and presents an approach to test interpretation. It concludes by describing alternative modalities for assessing exercise responses that are used in clinical practice.

PHYSIOLOGIC RESPONSES TO EXERCISE**EXERCISE AS A MULTISYSTEM PROCESS**

The ability to perform vigorous aerobic exercise requires tight integration of multiple systems. The respiratory

system serves as a ventilatory pump to move *oxygen* (O_2) from the atmosphere to the alveoli, where it efficiently moves across the alveolar walls to bind to hemoglobin. The heart must then pump the oxygenated blood to the exercising muscles, which extract oxygen to support adenosine triphosphate generation and muscle contraction. Muscle activity leads to production of *carbon dioxide* (CO_2), which must be delivered by the circulatory system to the lungs, where it diffuses across the alveolar walls and is eliminated via the ventilatory pump. The nervous system contributes at multiple stages in this process, providing important signals to increase ventilation and drive muscular contraction. All of these systems work in a highly coordinated manner to support exercise, and problems in one or more of these systems may manifest as dyspnea or exercise limitation.

NORMAL INDIVIDUALS

To appreciate changes in exercise performance associated with cardiopulmonary diseases, it is helpful to examine the normal physiologic responses to progressive exercise in four major areas—metabolic activity, hemodynamic responses, ventilatory responses, and gas exchange.

Metabolic Activity

Oxygen Consumption. Of all the parameters followed in clinical exercise testing, oxygen consumption, denoted as $\dot{V}O_2$ (a volume per time, e.g., mL/min), is perhaps the most useful for assessing overall exercise capacity. In essence, $\dot{V}O_2$ is the amount of fuel consumed in conducting work; the bigger or better the motor, the greater the maximum fuel consumption. To understand its utility in this regard, consider the determinants of $\dot{V}O_2$ using the Fick equation:

$$\dot{Q} = \frac{\dot{V}O_2}{CaO_2 - C\bar{v}O_2} \quad (1)$$

where \dot{Q} = cardiac output (mL/min), CaO_2 = arterial oxygen content (mL/dL), and $C\bar{v}O_2$ = mixed venous oxygen content (mL/dL). Rearranging the relationship as follows,

$$\dot{V}O_2 = \dot{Q}(CaO_2 - C\bar{v}O_2) \quad (2)$$

demonstrates that oxygen consumption is dependent on cardiac output; oxygen content, which is related to the

amount of hemoglobin and the partial pressure of oxygen; and the ability of the tissues to utilize oxygen. As a result, $\dot{V}O_2$ provides useful information about many of the systems necessary to perform sustained high-level exercise.

In addition to providing a sense of overall exercise capacity, the *maximum oxygen consumption* ($\dot{V}O_{2\max}$) achieved during progressive exercise is particularly useful for assessing cardiac function. Given that the arteriovenous oxygen content difference at maximum exercise is largely the same in normal individuals and those with cardiac disease,¹ the wide variation in $\dot{V}O_{2\max}$ across individuals is primarily determined by the variation in cardiac output. The greater the $\dot{V}O_{2\max}$, the greater an individual's cardiac output and vice versa.

Oxygen consumption can also be used to estimate stroke volume at maximum exercise. To understand this, [equation \(2\)](#) can be rewritten:

$$\dot{V}O_2 = HR \times SV(CaO_2 - C\bar{v}O_2) \quad (3)$$

and then rearranged as:

$$\frac{\dot{V}O_2}{HR} = SV \times (CaO_2 - C\bar{v}O_2) \quad (4)$$

The constancy of the arteriovenous oxygen content difference across normal individuals at maximum exercise means that the term $\dot{V}O_2/HR$, referred to as the *oxygen pulse* or *O₂ pulse*, can be used as a surrogate marker for stroke volume. The expected changes in normal individuals for this parameter, as well as cardiac output, are described as follows.

During progressive exercise to a symptom-limited maximum, $\dot{V}O_2$ increases linearly from resting values near 250 mL/min for an average-sized person until a plateau is reached at $\dot{V}O_{2\max}$. If a plateau is not identified, the term $\dot{V}O_{2\text{peak}}$ is often applied instead to denote that it may not represent the individual's potential maximum. In average sedentary individuals, $\dot{V}O_{2\max}$ is roughly 30 to 40 mL/kg/min at end-exercise, whereas fit athletes can attain values as high as 80 to 90 mL/kg/min. An individual's $\dot{V}O_{2\max}$ is influenced by a variety of factors including age and gender, which are discussed further later. With intensive training, unfit subjects can increase $\dot{V}O_{2\max}$ by 15% to 25%,^{2,3} but it is not possible to raise $\dot{V}O_{2\max}$ from an average level to an elite level. What tends to improve with training is the efficiency of work and ability to sustain high levels of power output. Genetic factors also play an important role in determining an individual's $\dot{V}O_{2\max}$ in the sedentary state,⁴ as well as in their response to training regimens.⁵ In clinical exercise testing, an individual's $\dot{V}O_{2\max}$ is typically expressed in reference to what would be predicted for their age and gender on the basis of data from large population studies. Numerous reference values have been published, but methodologic issues limit the wide applicability of many of them.⁶ As with all reference values, the normal range is dependent on the population studied. For example, Hansen and colleagues⁷ used studies from ex-shipyards workers who tended to be primarily older men while Nader and colleagues⁸ randomly selected their subjects to include equal numbers of men and women uniformly drawn across ages 20 to 80.

Carbon Dioxide Output. With increasing work, *carbon dioxide output* ($\dot{V}CO_2$) increases linearly from resting values,

which are near 200 mL/min for an average-size person, at about the same rate as oxygen consumption. Above the ventilatory threshold, an important exercise time point described further later, the rate of $\dot{V}CO_2$ output steepens as bicarbonate buffering of increasing lactate production leads to $\dot{V}CO_2$ production beyond that generated by aerobic metabolism.⁶

Respiratory Exchange Ratio. Defined as $\dot{V}CO_2/\dot{V}O_2$, the respiratory exchange *ratio* (R) remains largely stable between 0.8 and 0.9 in early to mid-exercise, with slight variation between individuals depending on the balance of dietary fats and carbohydrates. Just before and in the early stages of exercise, R can transiently increase due to anticipatory hyperventilation. Above the ventilatory threshold, $\dot{V}CO_2$ increases markedly and R increases above 1.0. With cessation of exercise, $\dot{V}O_2$ decreases abruptly while $\dot{V}CO_2$ remains elevated as tissue CO_2 stores continue to be eliminated. R can subsequently increase over 1 to 2 minutes to values as high as 1.3 to 1.5 before returning to baseline levels.

Ventilatory Thresholds. Normal individuals demonstrate a phenomenon termed the ventilatory threshold at about 50% to 60% of the $\dot{V}O_{2\max}$, although there is considerable interindividual variability in the timing of this phenomenon.^{6,9} This threshold marks a critical point in progressive exercise where blood flow to the exercising muscle is no longer sufficient to meet metabolic demands and the individual is transitioning from light-moderate to moderate-high-intensity exercise.¹⁰ Alternatively referred to as the *lactate threshold*, *gas exchange threshold*, or *anaerobic threshold*, the phenomenon is temporally related to an increase in lactic acid production and a decrease in pH, with considerable debate regarding the mechanisms for the increased lactate production^{11,12} and whether it happens suddenly or in a more continuous manner throughout exercise.¹³⁻¹⁵ As lactic acid dissociates, hydrogen ions are buffered by intracellular bicarbonate leading to further CO_2 generation beyond that associated with aerobic metabolism.^{10,16} This leads to a steep rise in the $\dot{V}CO_2$ versus work relationship, as well as the $\dot{V}CO_2$ versus $\dot{V}O_2$ relationship ([Fig. 26-1](#)). Identifying the change in slope of the latter relationship is referred to as the *V-slope method* and is a key step in CPET interpretation described later in this chapter.

With further increases in work beyond the ventilatory threshold, many individuals demonstrate a second ventilatory threshold, sometimes referred to as the *respiratory compensation point*, at which rising lactate concentrations cannot be buffered by intracellular bicarbonate, and *minute ventilation* ($\dot{V}E$) increases beyond that expected for the increase in $\dot{V}CO_2$, thereby leading to a respiratory alkalosis.^{10,16} This point, which may not be visible in all individuals due to interindividual variation in ventilatory responses to metabolic acidosis, can be identified by finding threshold responses in several ventilatory parameters described further later.

Further information on how to identify various thresholds is provided in "Interpreting Cardiopulmonary Exercise Tests" later.

Figure 26-1 The “V-slope” method for identifying the first ventilatory threshold. Before the threshold, oxygen consumption ($\dot{V}O_2$) and carbon dioxide production ($\dot{V}CO_2$) rise at the same rate. A best-fit line through these points is labeled L1 and is denoted in brown. After the threshold, $\dot{V}CO_2$ rises faster than $\dot{V}O_2$. A best-fit line through these points is labeled L2 and is denoted in blue. The point at which the two lines intersect denotes the $\dot{V}O_2$ at which the ventilatory threshold is reached.

Hemodynamic Responses

Cardiac Output. Cardiac output (mL/min), which can be either estimated from oxygen uptake using the Fick principle, measured invasively with a pulmonary artery catheter, or estimated noninvasively using inert gas rebreathing techniques,¹⁷ increases linearly with workload before reaching a plateau near peak exercise. The initial increase is a function of increasing stroke volume and heart rate, whereas the changes seen near peak exercise are driven primarily by increases in heart rate.¹⁸

Heart Rate. Due initially to decreased vagal tone and later to increases in sympathetic activity, heart rate (beats/min) increases linearly with increasing oxygen consumption. The heart rate reserve, defined as the difference between the maximum predicted heart rate and the heart rate achieved at peak exercise, is typically small or nonexistent in normal individuals (<20 beats/min), but this parameter is difficult to use in exercise test interpretation due to significant variability in maximum heart rates in normal age-matched individuals.^{6,19} Another measure of heart rate response, also termed the *heart rate reserve*, is the difference between the resting and maximal heart rate. This review uses the former definition.

Pulmonary Artery Pressure. Pulmonary artery pressure rises only modestly with progressive exercise in normal individuals, due to recruitment and distention of the pulmonary vasculature and the subsequent decrease in pulmonary vascular resistance. There is interindividual variability in observed responses,²⁰ with greater variability seen in older individuals.²¹ (For physiologic implications of pulmonary vascular recruitment see Chapter 4).

Stroke Volume. Characterized during CPET by the O_2 pulse (described earlier), stroke volume increases in early exercise before leveling off and possibly decreasing slightly at high levels of exercise.¹⁸ The initial increases are driven largely by mobilization of blood from lower extremity

venous capacitance vessels, whereas later, smaller increases result from increased inotropic activity.

Systemic Blood Pressure. Due to increases in cardiac output and vascular resistance in the skin and renal and splanchnic circulations, systemic blood pressure (mm Hg) increases with progressive exercise. Although vasodilation in exercising muscle beds limits the rise in diastolic pressure, systolic pressure rises significantly, particularly following the ventilatory threshold, and may reach values over 200 mm Hg at peak exercise.

Ventilatory Responses

Minute Ventilation. Due to an increase in both the respiratory rate and tidal volume, *minute ventilation* (\dot{V}_E , mL/min) rises throughout exercise with large increases seen following the ventilatory threshold. The tidal volume plateaus at about 50% to 60% of vital capacity, after which further increases in \dot{V}_E are driven solely by increases in respiratory rate.^{22,23} At peak exercise, \dot{V}_E is typically less than 80% of the predicted maximum, as estimated by the *maximum voluntary ventilation* (MVV) or *forced expiratory volume in 1 second* ($FEV_{1\text{ s}}$) $\times 40$.²⁴

Ventilatory Equivalents for Oxygen and Carbon Dioxide. The ventilatory response can be expressed as a function of the amount of ventilation per liter of oxygen consumed ($\dot{V}_E/\dot{V}O_2$, unitless) or per liter of exhaled carbon dioxide ($\dot{V}_E/\dot{V}CO_2$, unitless). Both ratios remain relatively steady (~24 to 30) through early exercise as ventilation rises proportionately with $\dot{V}O_2$ and $\dot{V}CO_2$. Due to the large increases in \dot{V}_E noted earlier, both parameters rise following the ventilatory threshold, peaking at around 35 to 40, with slightly greater increases seen in the $\dot{V}_E/\dot{V}O_2$.⁶ Both parameters may be elevated in early exercise in highly fit or anxious individuals but typically return to the normal range as exercise progresses and reach their nadir just before the ventilatory threshold. The range of ventilatory equivalents seen across normal individuals reflects the variability in respiratory drives in the population.

Dead Space Fraction. Because of increased tidal volumes and recruitment of the pulmonary vasculature resulting from increased pulmonary blood flow, the dead space fraction (V_D/V_T , unitless) normally decreases from 0.3 to 0.4 at rest to less than 0.2 at peak exercise, with the lowest values seen in younger individuals.⁶

Gas Exchange

Arterial and End-Tidal Partial Pressures of Carbon Dioxide. Despite increasing $\dot{V}CO_2$, the *arterial* (P_{aCO_2} , mm Hg) and *end-tidal partial pressure* (P_{ETCO_2} , mm Hg) of carbon dioxide remain near normal through early exercise due to the fact that alveolar ventilation rises proportionally with increasing $\dot{V}CO_2$. Low values may be seen in normal individuals who hyperventilate at the start of exercise, but these values typically normalize over the first few minutes of work. Following the ventilatory threshold, minute and alveolar ventilation rise out of proportion to the increase in $\dot{V}CO_2$ and, as a result, both arterial P_{CO_2} and P_{ETCO_2} decrease so that both values are nearly always less than 40 mm Hg at $\dot{V}O_{2\text{ max}}$.²⁵

Arterial and End-Tidal Partial Pressures of Oxygen and the Alveolar-Arterial Oxygen Difference. Below the ventilatory threshold, both the *end-tidal partial pressure of oxygen* (P_{ETO_2} , mm Hg), which is used as a surrogate measure of alveolar oxygen tensions, and the arterial (PO_2 , mm Hg) remain in the normal range, as do both the *arterial oxygen saturation* (SaO_2 , %) and the *alveolar-arterial oxygen difference* ($(A-a)PO_2$, mm Hg). As normal individuals pass their ventilatory threshold and approach maximum exercise, P_{ETO_2} increases due to alveolar ventilation that increases out of proportion to $\dot{V}O_2$.

While the alveolar PO_2 increases, the arterial PO_2 remains unchanged due to a lower $\dot{C}\bar{V}O_2$ and normal physiologic shunting. As a result, the $(A-a)PO_2$ increases slightly with heavy exercise. In a minority of highly fit individuals with high $\dot{V}O_{2max}$, arterial PO_2 and arterial SO_2 can decline in late exercise, a phenomenon referred to as *exercise-induced arterial hypoxemia*.^{26,27}

In CPET, the changes in many of the parameters described earlier can be identified from tabular data but are often best appreciated graphically using an approach developed by Wasserman and colleagues²⁸ in which nine separate graphs are displayed in a standardized format. The exercise responses in normal individuals described earlier are depicted in this manner in [Figure 26-2](#).

Changes with Age

Perhaps the most important change in exercise responses with aging is the decrease in maximum exercise capacity, which has been consistently reported in both cross-sectional^{29,30} and longitudinal studies.^{31,32} The expected rate of decline in $\dot{V}O_{2max}$ is unclear because documented rates vary from as low as 0.28 mL/kg/min/yr³¹ to as high as 1.04 mL/kg/min/yr,³³ with much of the variation attributable to differences in study design such as participant age, activity levels at the time of enrollment, and time intervals over which the study took place.³² Although some studies demonstrate a slower rate of decline in active individuals compared with sedentary individuals,³¹ others³⁴ have reported no effect of activity level on age-related declines in $\dot{V}O_{2max}$. Training programs in older sedentary individuals may be able to reverse much of the age-related decline in $\dot{V}O_{2max}$,³⁵ which accelerates in the later stages of life.³⁶

The etiology of the decrease in $\dot{V}O_{2max}$ varies depending on the time period examined. Between 20 and 50 years of age the decline in $\dot{V}O_{2max}$ is largely attributable to impaired peripheral oxygen extraction,³² whereas later changes relate to impaired peripheral extraction and decrements in maximum cardiac output due to an inability to raise stroke volume at maximum exercise.³⁷ Impairment in peripheral extraction may be due to decreases in lean body mass, age-related changes in skeletal muscle, or blood flow distribution at peak-exercise³²; the decline in cardiac output may represent the increasing incidence of comorbid conditions affecting cardiac performance.³⁷

Gender Differences

Comparisons of exercise responses in men and women are difficult because the majority of studies of physiologic responses to exercise have been performed in men. The available evidence shows that women have the same qualitative responses to exercise as men but have lower $\dot{V}O_{2max}$,

even after accounting for differences in lean body mass and training status.³⁸⁻⁴⁰ The mechanism for the observed differences remains unclear but may relate to differences in blood volume, heart size, hormonal and metabolic status, as well as autonomic nervous system regulation of the heart and vascular system.³⁸ Although some studies report slower age-related rates of decline in $\dot{V}O_{2max}$ in women compared with men, a recent large, cross-sectional study found no differences in this regard.³⁶

Ventilatory responses and gas exchange may also differ by gender, with some studies noting higher $\dot{V}E/\dot{V}O_2$ and $\dot{V}E/\dot{V}CO_2$ in women^{36,39,41} and others reporting higher $(A-a)PO_2$ in fit women at high levels of oxygen consumption.⁴² At high exercise intensities, women may also rely more heavily than men on fat oxidation as a fuel source and, as a result, may have a lower respiratory exchange ratio.^{43,44}

Obesity

Obese individuals lacking underlying cardiac or pulmonary disease display $\dot{V}O_{2max}$ lower than predicted for age and gender when expressed per kilogram of actual body weight but normal values when adjusted for ideal body weight. Because of the increased metabolic requirements resulting from their increased weight, however, several important differences are observed relative to nonobese individuals. $\dot{V}O_2$ for any given level of work is higher than in the nonobese, although the *rate of change in oxygen consumption per given change in work rate* ($\Delta\dot{V}O_2/\Delta WR$) remains the same.^{45,46} Obese individuals also have markedly increased $\dot{V}O_2$ when pedaling without resistance (unloaded pedaling) due to the energy demands of moving heavier legs against gravity⁴⁷ that is not reflected in the work rate reported on the cycle ergometer.

Another consequence of the increased metabolic requirements is an increase in $\dot{V}E$ for a given work rate compared with the nonobese due to the added CO_2 production from the additional tissues.⁴⁵ This is typically achieved by increasing respiratory rate rather than tidal volume, which some data suggest is decreased during exercise relative to normal individuals,^{48,49} possibly due to the increased inspiratory load associated with extra chest wall soft tissue. Obese individuals also have difficulty decreasing end-expiratory lung volume during exercise, likely as a result of expiratory flow limitation and air trapping.^{49,50}

The presence and magnitude of observed differences in these parameters may be a function of the degree of obesity, with greater differences seen in heavier individuals. The presence or absence of comorbid conditions may also be important, as demonstrated by Vanhecke and colleagues,⁵¹ who showed that obese individuals (average body mass index 49 ± 9 kg/m²) with *obstructive sleep apnea* (OSA) have lower $\dot{V}O_{2max}$, increased systolic and diastolic blood pressure, and impaired heart rate recovery compared with obese patients lacking OSA.

INDIVIDUALS WITH UNDERLYING CARDIOPULMONARY DISEASE

The physiologic responses to exercise described earlier are altered by the presence of underlying cardiopulmonary disease with different responses seen depending on the particular disease process.

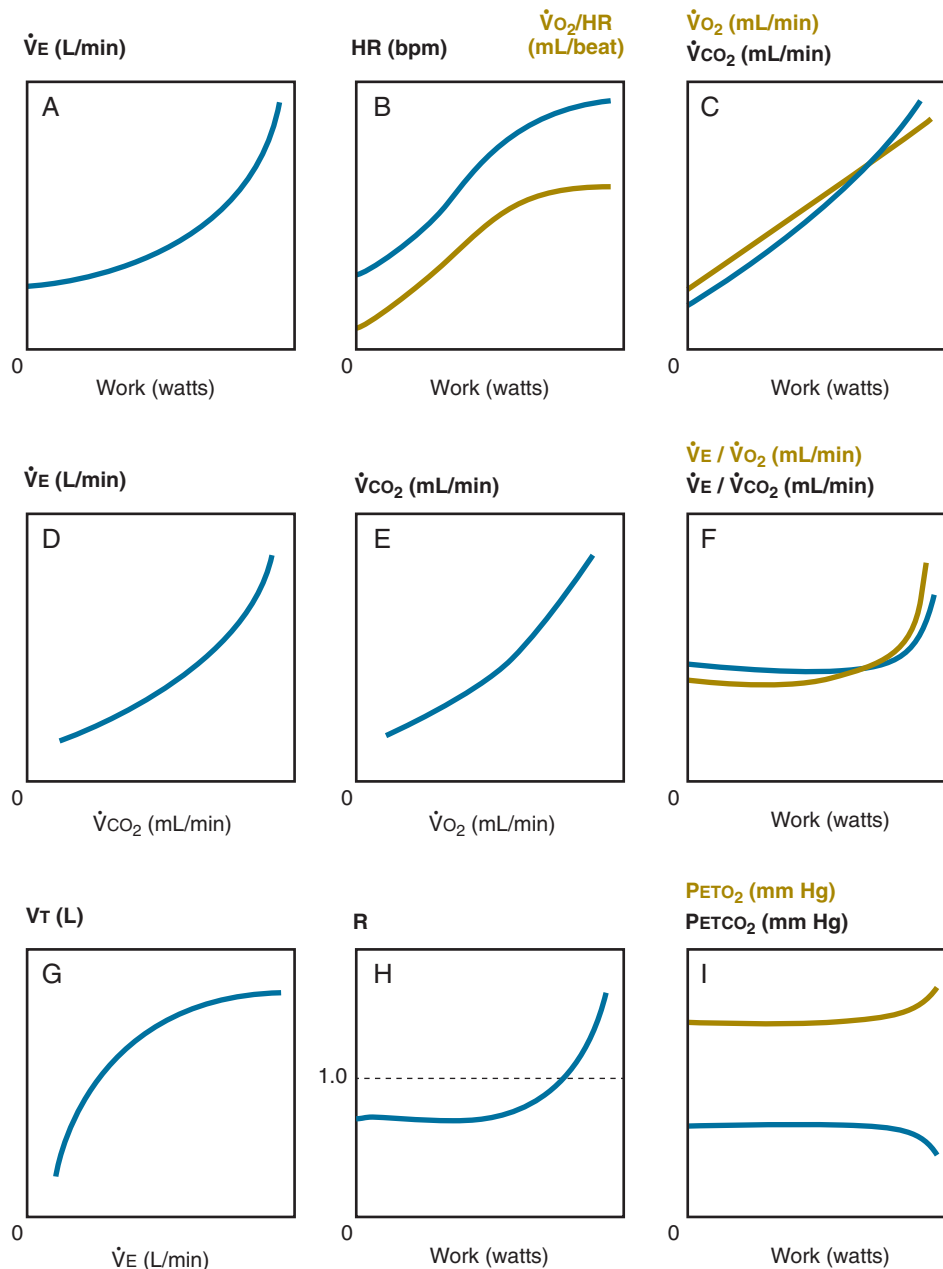

Figure 26-2 Nine-box plot displaying the expected responses to exercise in normal individuals. A, Minute ventilation (\dot{V}_E) versus watts; B, heart rate and oxygen pulse ($\dot{V}O_2/HR$) versus watts; C, oxygen consumption ($\dot{V}O_2$) and carbon dioxide production ($\dot{V}CO_2$) versus watts; D, \dot{V}_E versus $\dot{V}CO_2$; E, $\dot{V}CO_2$ versus $\dot{V}O_2$; F, ventilatory equivalents for oxygen ($\dot{V}_E/\dot{V}O_2$) and ventilatory equivalents for carbon dioxide ($\dot{V}_E/\dot{V}CO_2$) versus watts; G, tidal volume (V_T) versus \dot{V}_E ; H, respiratory exchange ratio (R) versus watts; I, end-tidal partial pressure of oxygen ($PETO_2$) and end-tidal partial pressure of carbon dioxide ($PETCO_2$) versus watts. Labels for the y-axis variables are presented on the top of each graph. Note that for the variables on the x- and y-axes the lowest values are in the lower left-hand corner of each plot. (Modified from Luks AM, Glenny RW, Robertson HT: Introduction to cardiopulmonary exercise testing. New York, 2013, Springer, Fig. 3-1.)

Heart Failure

As in normal individuals, maximum exercise in patients with heart failure is limited by the amount of blood that can be delivered to exercising muscle (i.e., they have a cardiac limitation to exercise). As a result, patients with heart failure demonstrate the same patterns of physiologic responses during progressive exercise to a symptom-limited maximum, albeit with significant differences in the magnitude of many of the observed responses.

The most important difference is the decrease in $\dot{V}O_{2max}$ and peak work rate relative to normal individuals. The

decrease in $\dot{V}O_{2max}$, which does not vary in magnitude between patients with systolic or diastolic dysfunction,^{52,53} results from an inability to raise cardiac output adequately due to impaired stroke volume responses with progressive exercise, denoted by the decreased $\dot{V}O_2/HR$. The ventilatory threshold is still usually reached at 50% to 60% of $\dot{V}O_{2max}$, but because $\dot{V}O_{2max}$ is decreased, the threshold is at a lower $\dot{V}O_2$ compared with normal individuals.

Many patients with heart failure compensate for the decreased stroke volume with an increase in heart rate for any given level of work. As a result, the heart rate reserve

at peak exercise is usually small (<20 beats/min). There is considerable variability in these responses, however, with some patients manifesting an inability to raise heart rate with progressive exercise, a phenomenon referred to as *chronotropic incompetence*, that persists even following discontinuation of β -blockers.⁵⁴ Patients with heart failure also may demonstrate an abnormal decline in heart rate on stopping exercise. In particular, heart rate recovery, which takes place as a result of reactivation of vagal tone⁵⁵ and is defined as the difference between peak heart rate and heart rate 1 minute into the recovery period, is decreased compared with normal individuals.

Altered ventilatory responses have also been described in patients with heart failure including increased airway resistance,⁵⁶ expiratory flow limitation at low work rates,⁵⁷ and an increased ventilatory reserve due to the fact that they are not able to do as much work and therefore do not require a high \dot{V}_E . Perhaps the most important difference, however, is the increased ventilatory inefficiency in patients with moderate to severe systolic or diastolic dysfunction, as indicated by an increased \dot{V}_E/\dot{V}_{CO_2} at the ventilatory threshold or an increased slope of the relationship between these parameters ($\Delta\dot{V}_E/\Delta\dot{V}_{CO_2}$).^{52,53} The most likely cause of this phenomenon is an increase in physiologic dead space due to impaired lung perfusion. Studies have shown, for example, that ventilatory inefficiency is related to abnormal pulmonary vascular tone⁵⁸ or right ventricular dysfunction⁵⁹ and actually improves following treatment with phosphodiesterase inhibitors and improvements in right ventricular function even when left ventricular function is unchanged.⁶⁰ Abnormal peripheral and central chemoreceptor sensitivity may also play a role in augmenting ventilation above that necessary for a given level of CO_2 production.⁶¹

Between 13% and 50% of patients with heart failure demonstrate another abnormal ventilatory response, referred to as *exercise oscillatory ventilation*, in which exercise ventilation is marked by periodicity similar to that seen in central sleep apnea.⁶²⁻⁶⁴ The mechanism for this is not clear but may relate to increased circulatory times, increased peripheral chemoreceptor sensitivity, increased ventilatory responses related to pulmonary congestion, and increased ergoreflex signaling (a peripheral reflex originating in skeletal muscle) related to muscle metabolic abnormalities.⁶⁴ Exercise oscillatory ventilation may be a marker of reduced cardiac index both at rest and during exercise⁶⁵ and may also improve following therapeutic interventions directed at the underlying heart failure such as treatment with sildenafil⁶⁶ or an exercise training program.⁶⁷ Despite these altered ventilatory responses, patients with heart failure have a normal (A-a)PO₂ and do not develop hypoxemia during exercise even though pulmonary artery occlusion pressure is elevated.^{68,69}

The pattern of exercise responses seen in patients with heart failure is displayed graphically in Figure 26-3.

Pulmonary Vascular Disease (for discussion of clinical aspects of pulmonary vascular disease, see Chapter 58)

In many respects, patients with pulmonary vascular diseases such as *pulmonary arterial hypertension* (PAH) and chronic thromboembolic pulmonary hypertension demonstrate physiologic responses to progressive exercise similar to those seen in patients with heart failure. Relative to

normal individuals, $\dot{V}_{O_{2max}}$, peak work rate and \dot{V}_{O_2}/HR are decreased while the ventilatory threshold is reached at a lower \dot{V}_{O_2} . Similar to patients with heart failure, the observed decline in $\dot{V}_{O_{2max}}$, which correlates inversely with mean pulmonary arterial pressure,⁷⁰ is due to an inability to raise cardiac output in response to exercise. The decreased cardiac output in patients with pulmonary hypertension exists because the right ventricle is unable to adequately preload the left ventricle due to high pulmonary vascular resistance.⁷¹ The fact that treatment with a pulmonary vasodilator such as sildenafil over a several-month period leads to improvements in both $\dot{V}_{O_{2max}}$ and \dot{V}_{O_2}/HR provides support for this concept.⁷²

These patients also demonstrate abnormal ventilatory responses including increases in \dot{V}_E/\dot{V}_{O_2} and \dot{V}_E/\dot{V}_{CO_2} ^{73,74} of greater magnitude than those seen in patients with heart failure of similar *New York Heart Association* (NYHA) functional class.⁷⁵ This ventilatory inefficiency can be attributed to increased physiologic dead space, as well as increased peripheral chemoreceptor stimulation from exercise-induced hypoxemia, and improves following several months of treatment with sildenafil.⁷² Depending on the extent of vascular occlusion and subsequent differences in physiologic dead space, the degree of ventilatory inefficiency, as measured by $\Delta\dot{V}_E/\Delta\dot{V}_{CO_2}$, may vary in magnitude between classes of pulmonary vascular disease patients, with higher values seen in patients with chronic thromboembolic pulmonary hypertension compared with PAH.⁷⁶

Aside from these similarities, an important difference between heart failure and pulmonary vascular disease is seen in the pulmonary artery pressure responses. Unlike in normal individuals or patients with heart failure where pulmonary artery pressure rises only modestly with increasing exercise, pulmonary vascular disease patients experience large rises in their pulmonary artery pressure with increasing blood flow due to impaired recruitment and distention of the pulmonary vasculature.^{77,78}

Physiologic dead space also changes in a different manner. Whereas V_D/V_T decreases from 0.3 to 0.4 at rest to less than 0.2 at peak exercise in normal individuals and patients with heart failure, it decreases only mildly and may even increase in patients with pulmonary vascular disease.⁷⁹ For example, Zhai and colleagues⁷⁶ reported V_D/V_T of 0.42 ± 0.13 and 0.53 ± 0.08 at peak exercise in patients with PAH and chronic thromboembolic pulmonary hypertension, respectively. This response is abnormal because perfusion of many lung units does not increase proportionately with alveolar ventilation due to impaired recruitment and distention. In addition, if patients develop right-to-left shunt by opening a patent foramen ovale during exercise, mean expired CO_2 decreases, leading to higher calculated V_D/V_T . As a result of the abnormal physiologic dead space, $PETCO_2$ is decreased relative to normal individuals at all stages of exercise in proportion to the patient's functional limitation.⁷⁰

A final important difference is the fact that patients with pulmonary vascular disease develop hypoxemia with progressive exercise even in the absence of resting hypoxemia. For example, Deboeck and colleagues⁷⁵ reported an oxygen saturation by pulse oximetry of $86 \pm 2\%$ at peak exercise in PAH patients compared with $96 \pm 3\%$ in patients with heart failure with similar NYHA functional class and D'Alonzo and colleagues⁷⁹ reported a mean (A-a)PO₂ of $45 \pm$

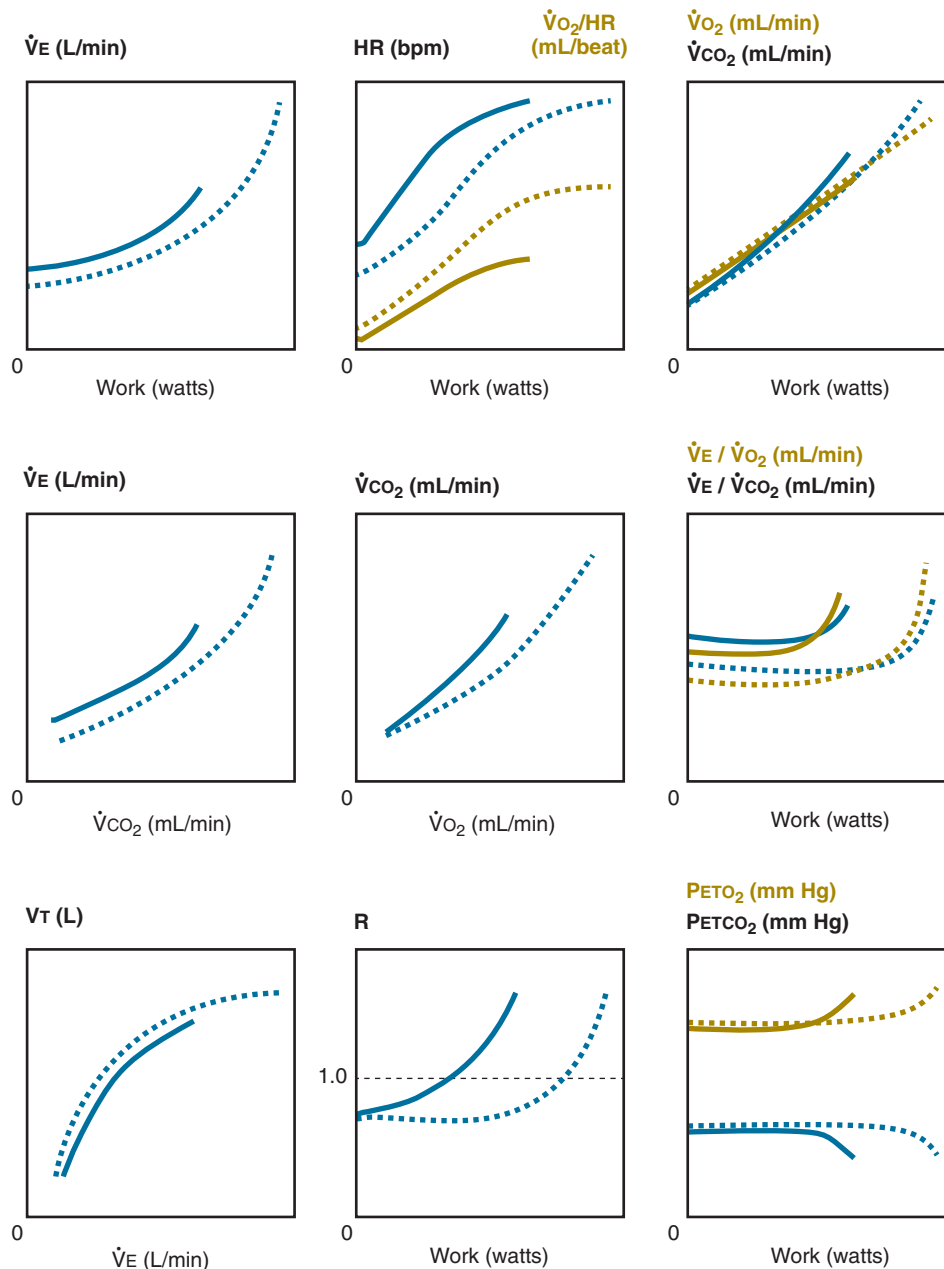

Figure 26-3 Heart failure compared to normal. Nine-box plot demonstrating expected physiologic responses to exercise in patients with cardiac limitation due to underlying heart failure (solid lines) compared with normal individuals (dotted lines). The layout of the graphs is the same as in Figure 26-2. (Modified from Luks AM, Glenn RW, Robertson HT: Introduction to cardiopulmonary exercise testing. New York, 2013, Springer, Fig. 3-3.)

17 mm Hg at peak exercise in idiopathic PAH patients, a higher value than typically seen in normal individuals.²⁵ In some patients, hypoxemia develops due to right-to-left shunting through an existing right-to-left communication or through a foramen ovale that opens during exercise due to the rise in pulmonary artery pressure, a finding that is predictive of death or need for transplant.⁸⁰ In other cases, hypoxemia may be due to diffusion limitation; red blood cell capillary transit time decreases with increasing pulmonary blood flow and may no longer be sufficient to ensure full equilibration between the capillary and alveolar P_{O_2} in the setting of the decreased functional capillary bed.⁸¹ This latter phenomenon is further accentuated by the low $\dot{C}\bar{V}O_2$ that exists due to the low cardiac output in this patient

population. (For clinical discussion of mechanisms of hypoxemia, see Chapter 4.)

The findings noted earlier pertain to patients with PAH at rest. Recent work suggests that measurement of hemodynamic variables during exercise may identify an intermediary phenotype between healthy individuals and overt PAH in which individuals develop mean pulmonary artery pressure greater than 30 mm Hg during exercise.⁸²⁻⁸⁴ This group may represent an early form of PAH. Standardized protocols to guide clinical practice regarding these patients are lacking at this time.⁸²

The pattern of exercise responses seen in patients with pulmonary vascular disease is displayed graphically in Figure 26-4.

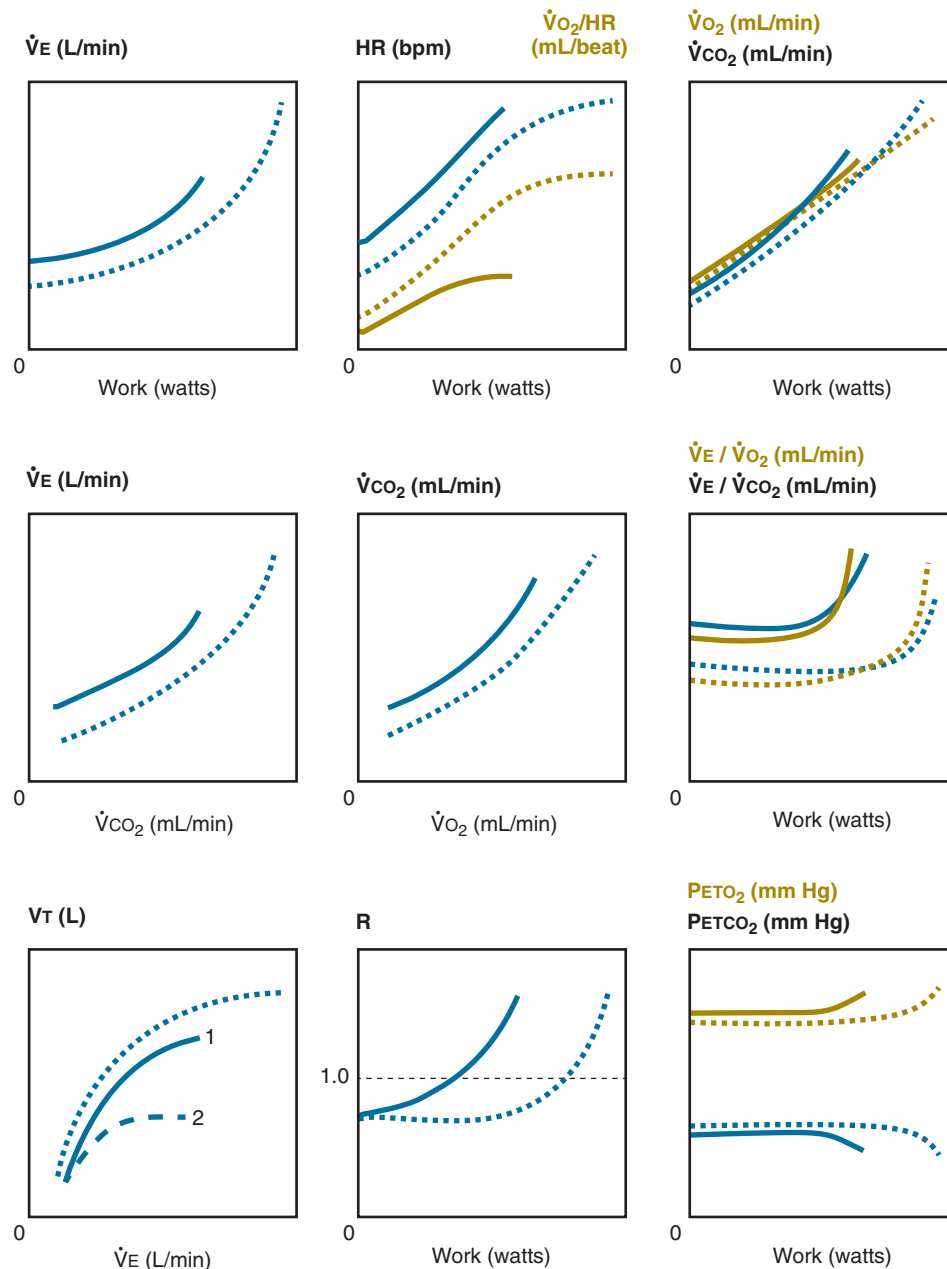

Figure 26-4 Pulmonary vascular or interstitial lung disease compared to normal. Nine-box plot demonstrating expected physiologic responses to exercise in patients with pulmonary vascular or interstitial lung disease patterns of limitation (solid lines) compared with normal individuals (dotted lines). Because the patterns of responses to exercise in each disease are similar, they are represented together above. In the graph in the lower left-hand corner, tidal volume (V_T) versus minute ventilation (\dot{V}_E), the solid blue line (Line 1) represents the expected response for a patient with pulmonary vascular disease while the dashed blue line (Line 2) represents the expected response for a patient with interstitial lung disease. (Modified from Luks AM, Glenn RW, Robertson HT: Introduction to cardiopulmonary exercise testing. New York, 2013, Springer, Fig. 3-6.)

Interstitial Lung Diseases (for discussion of clinical aspects of interstitial lung diseases, see Chapters 63–66)

Patients with *interstitial lung disease* (ILD) manifest physiologic responses during progressive exercise similar to those seen in patients with pulmonary vascular disease. In particular, they demonstrate reduced $\dot{V}O_{2max}$ and *maximum work rate* (W_{max}), increased $\dot{V}_E/\dot{V}O_2$ and $\dot{V}_E/\dot{V}CO_2$, reduced tidal volumes and increased respiratory rates, stable or increased V_D/V_T at end-exercise, and hypoxemia with reduced arterial PO_2 and increased $(A-a)PO_2$. Although patients with ILD may not have a decreased $\dot{V}O_2/HR$ and

the ventilatory threshold may not be decreased relative to their $\dot{V}O_{2max}$, these differences are usually not sufficient to distinguish between these two classes of patients on the basis of CPET alone and further studies such as *pulmonary function tests* (PFTs) and *computed tomography* (CT) imaging are necessary. Of note, when ILD develops in the setting of a collagen vascular disease, some of these responses can be observed before pulmonary involvement is evident on PFTs.⁸⁵

Debate exists regarding the underlying mechanism for the reduction in maximum exercise capacity. Hansen and

Wasserman,⁸⁶ for example, demonstrated that abnormal cardiac function due to pulmonary vascular pathology was more important than respiratory system factors in limiting exercise while Marciniuk and colleagues⁸⁷ used dead space loading during exercise to show that abnormal respiratory mechanics were the more important factor. Ventilatory equivalents are increased due to the increased dead space and the hypoxic ventilatory response, whereas exercise-induced hypoxemia, for which risk is increased in patients with a low *diffusion capacity for carbon monoxide* (DL_{CO}) on PFTs,⁸⁸ is due to a combination of *ventilation-perfusion* (\dot{V}_A/\dot{Q}) inequality and diffusion limitation.⁸⁹

Because the term *interstitial lung disease* represents a heterogeneous group of disorders, the physiologic responses to exercise vary on the basis of the specific disease process. Wells and colleagues,⁹⁰ for example, found increased dyspnea and hypoxemia in idiopathic pulmonary fibrosis compared with systemic sclerosis with ILD, while other studies have also shown worse hypoxemia, as well as increased pulmonary artery pressure responses in patients with idiopathic pulmonary fibrosis compared with sarcoidosis and other forms of ILD.^{91,92} The onset of pulmonary hypertension as a complication of ILD or an underlying systemic illness is associated with worse exercise tolerance, hypoxemia, and ventilatory inefficiency compared with otherwise similar patients with normal pulmonary artery pressures.^{93,94}

The pattern of exercise responses seen in patients with interstitial lung disease is displayed graphically in Figure 26-4.

Adult Congenital Heart Disease

With improvements in medical care, many patients with congenital heart disease are living into adulthood⁹⁵ and the increasing use of CPET in disease management has enhanced the understanding of their physiologic responses to exercise. Similar to that seen in patients with heart failure, patients with congenital heart disease demonstrate reductions in $\dot{V}O_{2max}$, peak work rate, and maximum heart rate and increases in $\dot{V}_E/\dot{V}CO_2$ compared with normal individuals.⁹⁶ In contrast, however, many congenital heart disease patients develop hypoxemia at end-exercise.⁹⁷ Given that many have coexisting pulmonary hypertension, one might also expect stable or increased \dot{V}_D/\dot{V}_T at end-exercise in many patients but this variable has not been reported in major series.

Owing to the diversity in the type and severity of congenital lesions, there is significant variability in the magnitude of observed changes in $\dot{V}O_{2max}$ and $\dot{V}_E/\dot{V}CO_2$ with the most serious abnormalities seen in those patients with Eisenmenger syndrome and complex lesions such as double-outlet ventricle or univentricular physiology.^{96,98} Patients with cyanosis and/or pulmonary hypertension also demonstrate greater reductions in these parameters when compared with patients lacking these problems.^{98,99} Importantly, functional impairment is not limited to those with significant lesions because even patients who are reportedly asymptomatic¹⁰⁰ or those with mild lesions such as repaired coarctation of the aorta demonstrate decreased $\dot{V}O_{2max}$ and increased $\dot{V}_E/\dot{V}CO_2$ compared with normal individuals.⁹⁶ Surgical repair is associated with improvements in exercise capacity,^{101,102} with the degree of improvement related in

some cases to whether the abnormality is repaired when the patient is a child or an adult.¹⁰³

Although much of the decrement in exercise capacity in these patients is attributable to cardiac and pulmonary vascular dysfunction related to the underlying defect or its repair, some patients are also limited by abnormal respiratory mechanics. Up to 50% of patients who have undergone surgical repairs have findings suggestive of restriction on spirometry,^{104,105} perhaps due to their often multiple thoracotomies and sternotomies. Those with abnormal spirometry show worse exercise capacity and NYHA functional class compared with those with normal spirometry.¹⁰⁵

Chronic Obstructive Pulmonary Disease

(for clinical discussion, see Chapters 43 and 44)

Patients with mild COPD may actually have normal exercise capacity while patients with moderate to severe COPD demonstrate decrements in $\dot{V}O_{2max}$ and peak work rate proportional to the severity of their disease as measured by *Global Initiative for Obstructive Lung Disease* (GOLD) stage.^{106,107} Beyond this decrease in exercise capacity, the pattern of physiologic responses to progressive exercise in COPD is different from that seen in patients with heart failure. Whereas exercise is limited in heart failure by an inability to deliver oxygen-rich blood to exercising muscles, patients with moderate-severe COPD are limited by altered respiratory mechanics; their ventilatory pump fails before the heart does.

The hallmark of ventilatory limitation in moderate to severe COPD is the fact that both arterial PCO_2 and $PETCO_2$ remain stable or increase at end-exercise due to an inability to raise minute and alveolar ventilation in response to increasing $\dot{V}CO_2$ and, when present, a metabolic acidosis. This phenomenon, which is present to a greater extent at higher GOLD stages of disease,¹⁰⁷ results from mechanical constraints due to dynamic hyperinflation during exercise (discussed further later) and altered ventilation-perfusion relationships.^{108,109}

In addition, \dot{V}_E at peak exercise will be at or close to the maximum predicted ventilation as measured by the MVV or $FEV_1 \times 40$, a marked contrast from normal sedentary individuals and those with heart failure in whom \dot{V}_E/MVV is normally less than 75% to 80%. Ventilation is typically higher for any given work rate and is usually marked by a high respiratory rate, low tidal volume, higher end-expiratory volume, and lower inspiratory capacity compared with normal individuals.¹¹⁰ Still another manifestation of ventilatory limitation is the absence of a ventilatory threshold in most patients with severe disease. Although patients with mild disease may still develop a metabolic acidosis¹¹¹ and even manifest a ventilatory threshold at lower levels of $\dot{V}O_2$ than normal individuals,¹¹⁰ patients with severe disease will not manifest such changes.¹¹² Along with the fact that peak heart rate is typically well below the maximum predicted heart rate in severe disease, the absence of the ventilatory threshold is strongly indicative of the fact that the ventilatory pump is failing before the circulatory pump.

Perhaps the most important reason for these manifestations of ventilatory limitation is a phenomenon referred to as *dynamic hyperinflation*. Due to expiratory flow limitation that develops even at low-moderate levels of exercise,

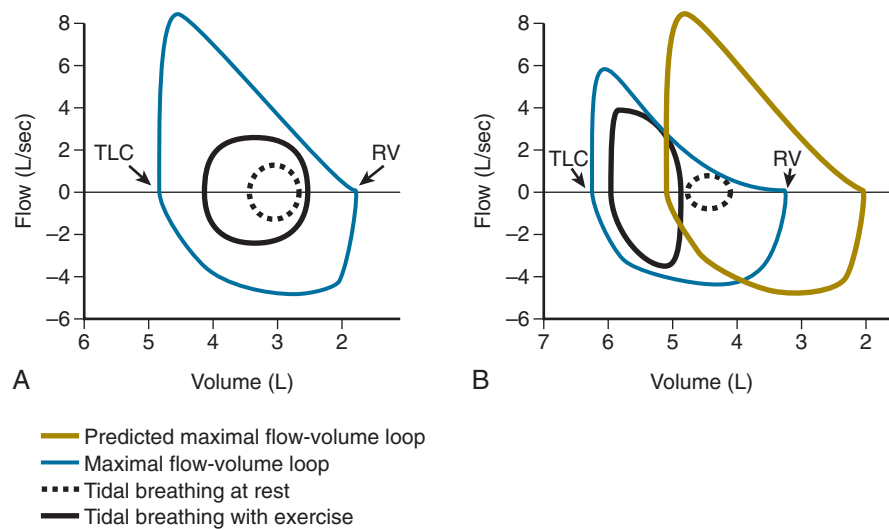

Figure 26-5 Expiratory flow limitation during exercise in patients with COPD. **A**, Typical pattern in normal individuals. During exercise, expiratory flow (black line) remains below the expiratory flow obtained in a forced vital capacity maneuver (blue line). **B**, Similar schemata for a patient with COPD. The flow-volume curve obtained in a forced vital capacity maneuver (blue line) is shifted to the left (higher volumes) and curvilinear, especially at low lung volumes, relative to the normal individual (brown line). With exercise, expiratory flow (black line) is equal to maximum expiratory flow over a portion of exhalation. RV, residual volume; TLC, total lung capacity.

patients with COPD must increase end-expiratory lung volumes and encroach on their inspiratory reserve volume in order to raise \dot{V}_E as metabolic activity increases (Fig. 26-5). The hyperinflation that results causes flattening of the diaphragm, which limits contractile strength, increases respiratory muscle fatigue, and causes increased dyspnea for any given level of ventilation.¹¹³ Interestingly, patients with dynamic hyperinflation have less locomotor muscle fatigue with exercise¹¹⁴ because the ventilatory pump fails before the nonrespiratory muscle groups face significant loads.

Dynamic hyperinflation also has significant hemodynamic effects, including alterations in cardiac preload and afterload that subsequently impair cardiac function and manifest as a decrease in $\dot{V}O_2/\text{HR}$. The magnitude of this problem inversely correlates with the increase in end-expiratory lung volumes,¹¹⁵ and improvement can be seen following interventions that decrease dynamic hyperinflation such as *lung volume reduction surgery* (LVRS).¹¹⁶ Impaired right ventricular function may also result from increased pulmonary vascular resistance due to hypoxic pulmonary vasoconstriction and structural changes in the pulmonary circulation.¹¹⁷ In fact, in patients whose COPD is complicated by pulmonary hypertension (mean PAP ≥ 40 mm Hg), impaired circulatory function is the primary factor limiting exercise rather than the ventilatory constraints.¹¹⁸ Some patients with COPD also manifest chronotropic incompetence,¹¹⁹ which may limit the cardiac response to exercise. The increased work of breathing may also contribute to exercise limitation by limiting blood flow to locomotor muscles.¹²⁰

Another important feature of progressive exercise in patients with COPD is the onset of hypoxemia with a widened (A-a) PO_2 . This problem correlates with reductions in diffusing capacity,¹²¹ is more common when the COPD is due to emphysema rather than to chronic bronchitis, is more severe in patients with pulmonary hypertension,¹²² and is more prominent with walking as opposed to cycling.¹²³

The predominant mechanism is \dot{V}_A/\dot{Q} inequality, the effects of which are magnified by reductions in $\text{C}\dot{V}O_2$ during exercise.⁸⁹ Depending on the distribution of blood flow and ventilation, however, \dot{V}_A/\dot{Q} inequality may actually improve during exercise, which accounts for the observation that some patients with COPD actually see improvement in arterial PO_2 during exercise testing.^{124,125}

The pattern of exercise responses seen in patients with ventilatory limitation due to COPD is displayed in Figure 26-6.

CARDIOPULMONARY EXERCISE TESTING

INDICATIONS AND CONTRAINDICATIONS

The indications for CPET sort into five general areas: determining the etiology of exercise limitation, assessing functional status, stratifying risk for surgery, prognosticating outcomes related to specific diseases, and creating individualized exercise prescriptions for rehabilitation programs. The list of indications for CPET (Table 26-1) is largely compiled from expert opinions, and the evidence for the utility of CPET varies by indication, each of which is reviewed later.

Determining Etiology of Dyspnea and Exercise Limitation (for discussion of dyspnea see Chapter 29)

Evaluating Dyspnea. Dyspnea with exercise is a subjective complaint that is the end result of various diseases. When the cause of dyspnea is not apparent from history, physical examination, laboratory testing (including a hemoglobin concentration and resting arterial blood gas), chest imaging, and PFTs, CPET can be used to quantify a patient's exercise limitation and determine which system is limiting exercise. Although CPET on occasion can narrow the differential list down to a single limiting system, such as

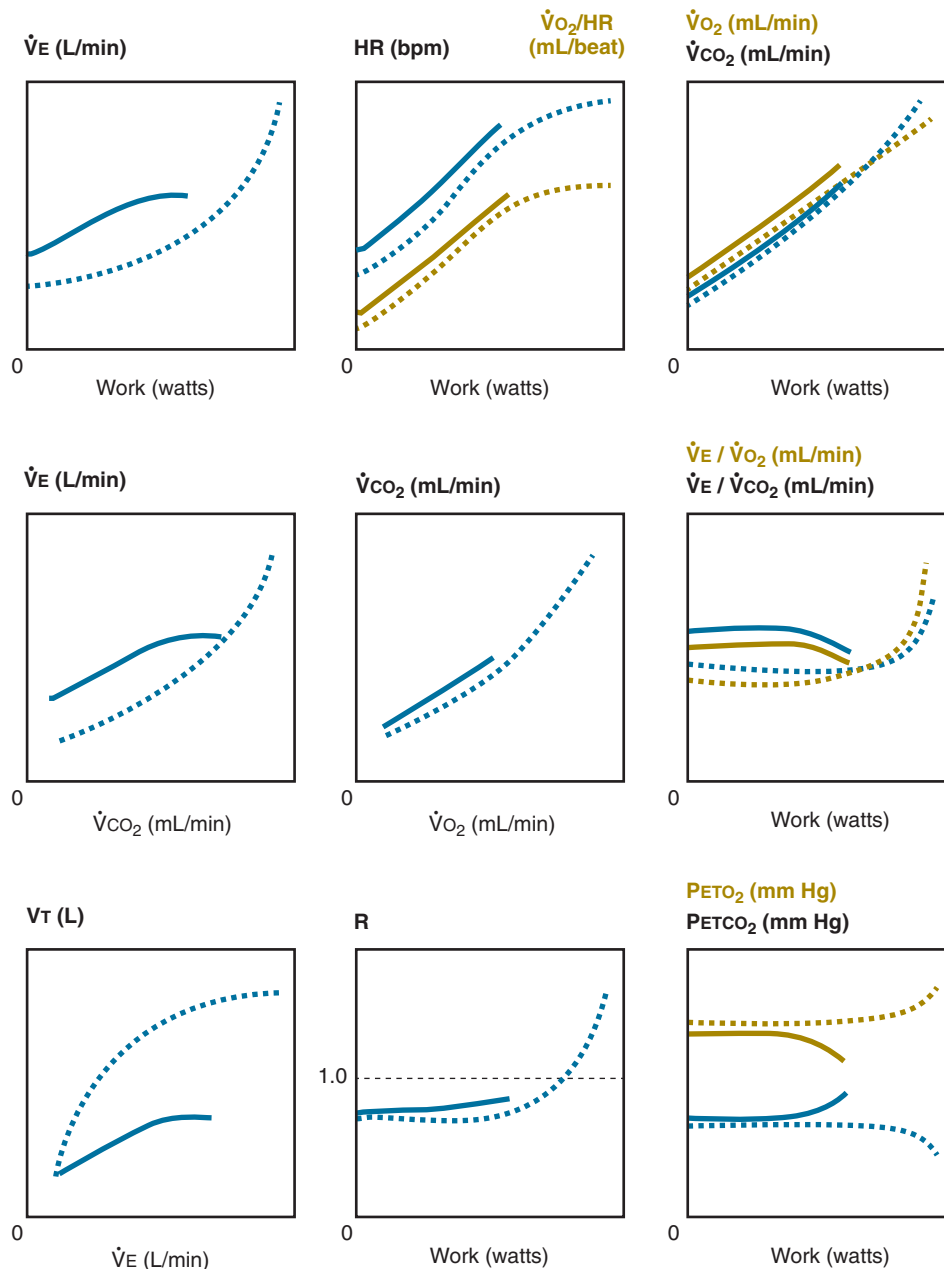

Figure 26-6 COPD compared to normal. Nine-box plot demonstrating expected physiologic responses to exercise in patients with ventilatory limitation due to COPD (solid lines) compared with normal individuals (dotted lines). (Modified from Luks AM, Glenn RW, Robertson HT: Introduction to cardiopulmonary exercise testing. New York, 2013, Springer, Fig. 3-4.)

in patients with chronotropic incompetence or myocardial ischemia, it is most useful in identifying the next best studies to pursue in making a definitive diagnosis.

The first step in using CPET to evaluate dyspnea is to determine if the patient's subjective complaints and description of their limitations are appropriate for the degree of work they are able to perform. It is therefore imperative that the patient gives a maximal effort during the CPET. An arterial blood gas at the end of exercise can be helpful in this setting to determine if the individual gave a good effort, was ventilatory limited, had excess dead space, or was hyperventilating. It can also be helpful to use a dyspnea scale¹²⁶ during a ramped exercise protocol to

quantify and link a patient's sense of dyspnea with the level of work being performed. It is also important to ask the patient if the CPET protocol reproduced the patient's symptoms of dyspnea. This postexercise questioning often helps define the subjective complaints and narrow the differential diagnosis.

As described earlier, the pattern of response to exercise can be used to determine which system is limiting exercise and likely creating the sense of dyspnea. In a group of 50 patients referred for CPET with unexplained dyspnea,¹²⁷ for example, broad diagnoses of cardiac limitation, pulmonary limitation, obesity and/or deconditioning, and psychogenic dyspnea were identified.

Table 26-1 Indications and Contraindications for Cardiopulmonary Exercise Testing

Indications	Contraindications
Determining the etiology of dyspnea and exercise limitation Evaluating dyspnea Evaluating exercise limitation Evaluating combined cardiac and pulmonary disorders Diagnosing exercise-induced bronchoconstriction Assessing functional status and quantifying impairment Risk stratification Assessment for thoracic surgery Evaluation for lung volume reduction surgery Assessment for major general surgery Prognosticating outcomes Evaluation of heart failure and prognostication for transplantation Assessment of adult congenital heart disease Assessment of pulmonary arterial hypertension Exercise prescriptions for rehabilitation programs	ABSOLUTE Active myocardial ischemia (unstable angina, myocardial infarction within 30 days) Acute heart failure exacerbation Exercise-induced syncope Uncontrolled arrhythmias Severe aortic stenosis Acute endocarditis, myocarditis, pericarditis Acute aortic dissection or suspected dissecting aortic aneurysm Acute pulmonary embolism or lower extremity deep venous thrombosis Active COPD exacerbation or uncontrolled asthma Active pulmonary edema Oxygen saturation < 85% breathing air at rest Acute respiratory failure RELATIVE Severe pulmonary hypertension Left main coronary artery stenosis Moderate stenotic valve disease Severe hypertension (SBP > 200 mm Hg, DBP > 120 mm Hg) Hypertrophic cardiomyopathy High-degree atrioventricular block Severe electrolyte abnormalities Tachyarrhythmias or bradyarrhythmias Advanced or complicated pregnancy Implanted cardiac defibrillator that cannot be interrogated or temporarily reset due to inaccessibility of an individual qualified to do this (e.g., device manufacturer representative)

DBP, diastolic blood pressure; SBP, systemic blood pressure.

Table 26-2 Estimating $\dot{V}O_{2\max}$ from the History

Activity Limitations	Approximate $\dot{V}O_{2\max}$ (mL/kg/min)
Participates in competitive sports with sustained activity like rowing, basketball, and soccer.	>40
Engages in regular endurance training. Tolerates sustained heavy labor well; can play recreational soccer or full-court basketball without slacking or run at an 8-minute/mile pace	
Tolerates sustained heavy labor well; can play recreational soccer or full-court basketball	35–40
Participates in recreational cross-country skiing or half-court basketball with minimal limitation	30–35
Performs heavy labor with difficulty; downhill skiing somewhat limited by fatigue	25–30
Heavy housework or yard work causes dyspnea; cannot play singles tennis	20–25
Dyspnea with two flights of stairs at own pace; cannot play golf while carrying bag or pulling a cart	17–20
Unable to vacuum average room or change sheets without rest	14–17
Difficulty walking slowly with peers in shopping mall	12–14
Dyspnea while brushing hair, dressing, showering	<12

Evaluation of Exercise Limitation. Patients presenting with exercise limitation rather than dyspnea as a complaint state that they just cannot perform the amount of work that they could do in the past. These complaints tend to be more vague and difficult to sort out by the usual history and standard studies. CPET is useful in this setting to quantify the amount of work that an individual can perform in a supervised test and compare it with what they say they can do during the activities of daily living. Table 26-2 provides a rough estimate of the maximal oxygen consumption that correlates with the level of exercise a patient states he or she can perform.¹²⁸ It is important to keep in mind that there is a broad spectrum of exercise capabilities across the normal population. Although an individual may have a “normal” exercise study as judged by the maximal oxygen

consumption, the observed response for any individual may represent a significant decline in his or her exercise performance from a previous supranormal level.

Evaluating Combined Cardiovascular and Pulmonary Disorders. When individuals have underlying diseases in more than one system, CPET can help determine which system is primarily responsible for their exercise limitation and guide patient management. For example, in a patient with both aortic stenosis and COPD, CPET can help determine whether or not to proceed with valve repair. Were such a patient to be primarily limited by his or her ventilatory capacity, repairing the aortic valve may not be indicated, because following surgery the individual would still be significantly limited by his or her ventilatory

capacity. While assisting in identifying the primary limiting system, CPET cannot quantitatively partition the degree of limitation due to each of the affected systems.

Diagnosing Exercise-Induced Bronchoconstriction. CPET can be used to diagnose exercise-induced bronchoconstriction, a transient, reversible bronchoconstriction that develops during or after strenuous exercise, which is present in more than 10% of the general population and up to 90% of persons previously diagnosed with asthma.¹²⁹ Although administration of inhaled bronchoprovocatory agents such as methacholine or mannitol can be used to make the diagnosis (see Chapter 25), exercise challenge using free running, treadmill, or cycle ergometry has been used to elicit exercise-induced bronchoconstriction since the 1970s¹³⁰ and, along with eucapnic voluntary hyperventilation, is a more sensitive and specific testing modality.¹³¹ Exercise testing for this purpose requires specialized equipment, personnel, and the ability to exercise at 85% to 95% maximum heart rate with dry medical grade air and high flow rates (>100 L/min)¹³² and should be performed according to published guidelines.^{133,134}

Due to the logistical issues associated with exercise challenges, the International Olympic Committee Medical Commission recommends eucapnic voluntary hyperventilation¹³¹ as the initial testing modality followed by CPET if eucapnic voluntary hyperventilation is nondiagnostic.¹³⁵

Assessing Functional Status and Degree of Impairment

Quantitative measures of exercise capacity are also useful in determining eligibility for disability because static tests such as PFTs and cardiac ejection fraction by echocardiography do not correlate well with exercise capacity.¹³⁶⁻¹³⁸ For example, in a heterogeneous population of subjects, the variables FEV₁ and DL_{CO} poorly predicted the maximal O₂ consumption,¹³⁹ likely due to the fact that many individuals have cardiovascular limitations not captured by either of these PFT parameters. Despite these issues, the American Thoracic Society statement on the evaluation of impairment and disability¹⁴⁰ states that impairment can be determined from standard pulmonary functions studies in most cases and that further testing with CPET may be helpful in selected situations. Importantly, quantifying impairment informs but does not define disability because disability assessment requires social, economic, environmental, and other input.¹⁴¹ Largely on the basis of empirical knowledge, rough estimates of the work that an individual should be able to perform have been proposed (Table 26-3).

Risk Stratification

Risk Assessment for Thoracic Surgery. A number of studies have looked at preoperative CPET to determine whether patient outcomes can be predicted on the basis of exercise capacity.¹⁴²⁻¹⁴⁵ Although the available studies have not used randomized, controlled designs and generally involve small numbers of patients from single centers, they do show an association between exercise capacity and clinical outcomes following major surgery. Drawing on this evidence, an expert panel of the American College of Chest Physicians¹⁴⁶ devised an algorithm that incorporates CPET along with the Thoracic Revised Cardiac Risk Index,¹⁴⁷

Table 26-3 Impairment Determined by Cardiopulmonary Exercise Testing

Vo _{2max} (mL/kg/min)	Description of Work
>25	Capable of all but most physically demanding jobs
15–25	Able to work at the specific job that does not require frequent and extended work above 40% of maximum Vo ₂
<15	Unable to perform most jobs

Based on recommendations from the American Thoracic Society: Evaluation of impairment/disability secondary to respiratory disorders. *Am Rev Respir Dis* 133(6):1205–1209, 1986.

spirometry, DL_{CO}, and performance on stair climbing or shuttle walk testing to guide selection of the appropriate therapeutic approach in lung cancer patients (Fig. 26-7). The general approach can probably be used as a foundation for any lung resection surgery. Patients who require CPET as part of this algorithm are deemed low risk (expected risk of mortality < 1%) if the Vo_{2max} is greater than 20 mL/kg/min or more than 75% of predicted. They are considered high risk (expected mortality > 10%) if their Vo_{2max} is less than 10 mL/kg/min or less than 35% of predicted. The expert panel gave this algorithm a strong recommendation on the basis of their experience, although it should be recognized there are no data demonstrating the utility of this approach or comparing it with other risk stratification algorithms that do not use CPET.¹⁴⁸

In addition to risk stratification, CPET provides a wealth of information that helps identify those systems responsible for reduced aerobic capacity. Once those systems are identified, corrections can be implemented to improve patient fitness and minimize surgical risk.¹⁴⁹ Such steps might include, for example, coronary revascularization, medical treatment, or physical rehabilitation.

Evaluation for Lung Volume Reduction Surgery. The landmark National Emphysema Therapy Trial¹⁵⁰ demonstrated that LVRS was clearly of benefit, but only for the subset of patients defined by their reduced exercise capacity, when using a modified but formalized exercise protocol. The study participants underwent a maximal CPET on a cycle ergometer while wearing a face mask delivering an FiO₂ of 0.30 and pedaling for 3 minutes without resistance, followed by progressive increases in work rate by 5 or 10 watts/min. Those patients with a low exercise capacity, here defined as less than 25 W for women and 40 W for men, were found to benefit from LVRS.

Risk Assessment for Extrathoracic Surgery. A number of studies have investigated the utility of performing CPET for risk stratification or identification of other comorbidities that could be addressed in the perioperative period. Such an approach has been investigated in a variety of groups undergoing major surgery including those undergoing abdominal-aortic repair,^{151,152} hepatic transplantation,¹⁵³ upper gastrointestinal surgery,¹⁵⁴ as well as elderly patients undergoing intra-abdominal surgery.¹⁵⁵ Seven of the nine studies included in a review of this issue¹⁵⁶ found higher mortality in patients with lower Vo_{2max}. In one of the

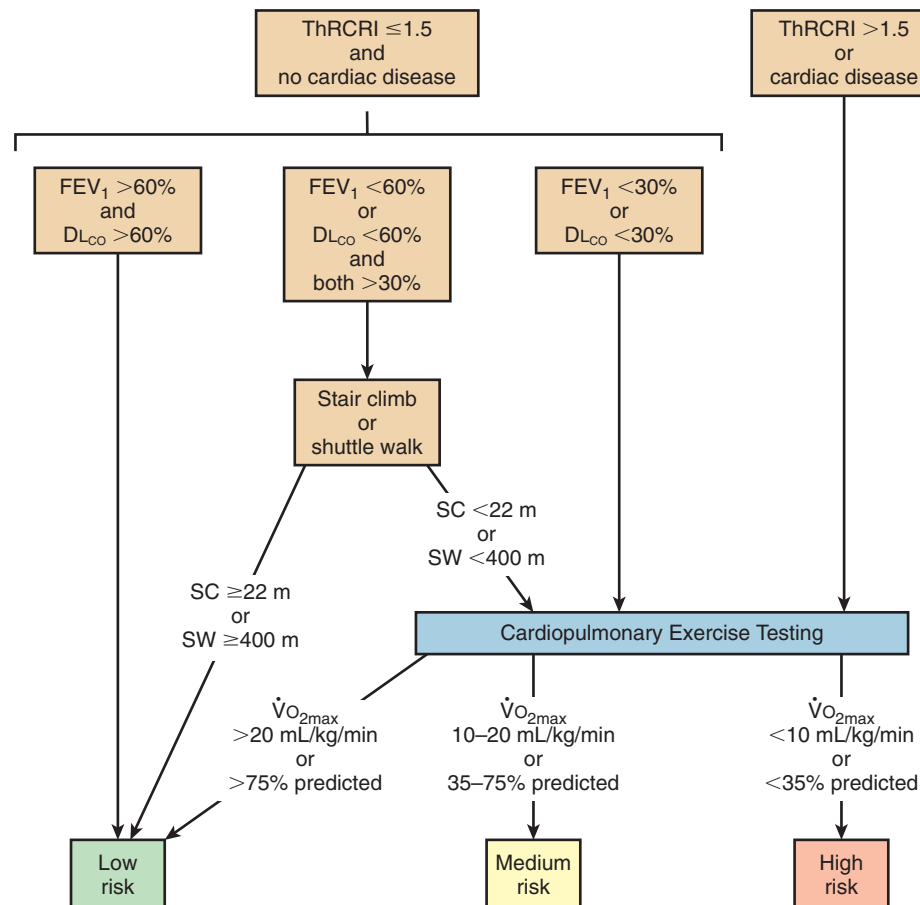

Figure 26-7 Algorithm for risk stratification for thoracic surgery in patients with lung cancer. The Thoracic Revised Cardiac Risk Index (ThRCRI) uses a point system in which a pneumonectomy, previous heart disease, and prior stroke or transient ischemic attack receive 1.5 points each and a creatinine greater than 2 mg/dL is given 1 point. The forced expiratory volume in 1 second (FEV₁) and diffusion capacity for carbon monoxide (DL_{CO}) cutoffs are based on the predicted postoperative values that are calculated by multiplying the preoperative measured values by the fraction of lung remaining after resection. SC, stair climb; SW, shuttle walk.

studies,¹⁵⁵ $\dot{V}O_2$ at the ventilatory threshold measured preoperatively was used to determine the appropriate hospital location for postoperative care; a $\dot{V}O_2$ less than 11 mL/kg/min was the cutoff in the postoperative intensive care unit and a marker of increased mortality. Despite this evidence, there are no prospective studies documenting survival benefit or cost-effectiveness for using CPET in this manner.

Prognosticating Clinical Outcomes

In normal subjects without specific diseases and in general among individuals with disease, survival is associated with a higher exercise capacity.^{157,158} However, interventional studies have not been conducted to determine whether training to improve $\dot{V}O_{2max}$ increases life expectancy. Some of the patient populations for whom $\dot{V}O_{2max}$ and other data derived from CPET provide prognostic information are described as follows.

Heart Failure. $\dot{V}O_{2max}$ is the most objective data available for assessing exercise capacity in individuals with heart failure. When the contribution of heart failure to exercise limitation is uncertain, the American College of Cardiology and the American Heart Association recommend CPET in patients presenting with heart failure to guide management and determine whether heart failure is the cause of exercise

limitation.¹⁵⁹ A number of early studies¹⁶⁰⁻¹⁶² documented a progressive decline in survival with decreasing $\dot{V}O_{2max}$. More recent studies have shown similar relationships between $\dot{V}O_{2max}$ and mortality.^{163,164} Importantly, the inclusion of patients treated with β -blockers in recent series¹⁶⁵⁻¹⁶⁷ now suggests that a threshold of less than 14 mL/kg/min should be considered for heart transplantation. Most studies investigating the utility of $\dot{V}O_2$ for prognostication in heart failure use the traditional weight normalized values (mL/kg/min), but due to the obesity “epidemic,” the reported oxygen consumption data may be inappropriately low and decisions for heart transplantation may be skewed toward the obese. Correcting $\dot{V}O_2$ for lean body mass may improve prognostication.^{168,169}

Other CPET variables may be better predictive tools than $\dot{V}O_{2max}$. For example, a series of studies show that $\dot{V}E/\dot{V}CO_2$ or the $\dot{V}E/\dot{V}CO_2$ slope¹⁷⁰⁻¹⁷⁵ is an accurate predictor of mortality and may improve predictive capabilities of models used to guide heart failure management.¹⁷⁶ Although most of these studies identify a single threshold above which the $\dot{V}E/\dot{V}CO_2$ indicates a higher mortality in patients with heart failure, a more recent analysis by Arena and colleagues¹⁷⁰ created four classes on the basis of the $\dot{V}E/\dot{V}CO_2$ slope and reported that event-free survival was significantly different across the four classes. When combined with the peak

Figure 26-8 Cardiac events associated with exercise test results. The likelihood of a major cardiac event was higher in those with a low peak oxygen consumption ($\dot{V}O_2$) and high slope of ventilatory equivalents for carbon dioxide ($\dot{V}E/\dot{V}CO_2$) from a cardiopulmonary exercise test. Patients with a peak $\dot{V}O_2$ of less than 8.9 mL/kg/min and a $\dot{V}E/\dot{V}CO_2$ slope greater than 45 had a greater than 70% chance of having a cardiac event over a 2-year period. (From Arena R, Myers J, Abella J, et al: Development of a ventilatory classification system in patients with heart failure. *Circulation* 115(18):2410–2417, 2007.)

$\dot{V}O_2$, the $\dot{V}E/\dot{V}CO_2$ slope further differentiates which patients are at risk for major cardiac events (Fig. 26-8). On the basis of the most recent literature, individuals with a $\dot{V}O_{2max}$ less than 10 mL/kg/min or a $\dot{V}E/\dot{V}CO_2$ slope greater than 40 have the poorest prognosis.¹⁷⁷

Other parameters shown to be associated with outcomes such as mortality, need for transplantation, or need for device implantation in patients with heart failure include heart rate recovery,¹⁷⁸⁻¹⁸¹ oxygen uptake efficiency,¹⁸²⁻¹⁸⁴ exertional oscillatory ventilation,^{63,64,185} heart rate variability,^{186,187} and blood pressure response.^{188,189} A number of different groups have attempted to use multiple CPET parameters¹⁹⁰⁻¹⁹² or combined CPET parameters with other medical information (renal function, echocardiography, questionnaires)^{164,193} to guide prognostication as an alternative to the traditional strategy of using a single parameter.

Adult Congenital Heart Disease. CPET has emerged as a valuable tool in the management of patients with congenital heart disease.⁹⁶ It aids in risk stratification and determining the need and timing of therapeutic interventions. CPET is thought to be of special importance in this patient population because self-reported exercise capacity has been shown to be of poor predictive value¹⁹⁴ and functional limitation can be documented in those who are asymptomatic.¹⁰⁰ Similar to patients with heart failure described earlier, $\dot{V}O_{2max}$ ¹⁰⁰ and $\dot{V}E/\dot{V}CO_2$ ¹⁹⁵ are strong predictors of mortality. Due to a variety of factors, including the significant heterogeneity of adult congenital heart disease, the decision of when to consider heart transplantation in the adult patient with congenital heart disease is particularly complex but CPET can be useful.^{98,196}

Pulmonary Arterial Hypertension. Assessment of exercise capacity can also be used to assess prognosis and response to treatment in PAH patients. For example, Sun and colleagues⁷⁴ found that peak work rate, $\dot{V}O_{2max}$, ventilatory threshold, O_2 pulse, and slope of $\dot{V}E/\dot{V}CO_2$ were all correlated with NYHA class. Yasunobu and colleagues⁷⁰ reported that $PETCO_2$ progressively decreased as the disease severity increased and directly correlated with changes in mean pulmonary artery pressure. Other studies have demonstrated a relationship between survival and $\dot{V}O_{2max}$ and $\dot{V}E/\dot{V}CO_2$ ^{71,197,198} and that persistent exercise-induced right-to-left shunt and poor ventilatory efficiency during serial assessments were highly predictive of poor outcomes in patients with PAH.⁸⁰

Although CPET is a safe^{74,199} and effective means to grade the severity of exercise limitation, assess prognosis, and measure response to therapy,²⁰⁰ the use of CPET is limited in most PAH trials due to a number of practical issues. Instead, most trials rely on the simple, less expensive, and reproducible 6-Minute Walk Test (6MWT, described in greater detail later), which, like CPET, provides prognostic information.^{201,202} Improvement in the 6MWT following therapeutic intervention may also be associated with a decrease in mortality,^{203,204} although not all studies have validated this finding.²⁰⁵

Exercise Prescriptions for Cardiac and Pulmonary Rehabilitation Programs (for discussion of clinical

aspects of rehabilitation, see Chapter 105)

Given that the intensity of aerobic exercise is linked to both the improvement in exercise capacity and the risk of adverse events during exercise, a joint position statement of the European Association for Cardiovascular Prevention and Rehabilitation, the American Association of Cardiovascular and Pulmonary Rehabilitation, and the Canadian Association of Cardiac Rehabilitation stressed the importance of functional evaluation using exercise testing before starting an aerobic training program.¹⁰ Although there are many methods for creating individualized training programs, these guidelines propose that CPET be the gold standard for assessment and prescription of exercise intensity. The committee's goal is to shift from a "range-based" to a "threshold-based" aerobic exercise intensity prescription to maximize the benefits obtainable by the use of aerobic exercise training in cardiac rehabilitation.¹⁰

Similarly, the American Thoracic Society and the European Respiratory Society statement on pulmonary rehabilitation²⁰⁶ states that before initiating rehabilitation for COPD, CPET should be considered as part of a thorough assessment to identify factors contributing to exercise limitation, to determine the exercise prescription, and to evaluate safety by monitoring ECG and blood pressure for potential risks.²⁰⁷ Casaburi and colleagues,²⁰⁸ for example, have shown that high-intensity training programs (80% of W_{max} in the incremental test) are more effective than less intense programs (50% of W_{max}) in patients with COPD. In the absence of cardiovascular limitation, the training program in these individuals may begin at or above the intensity of the ventilatory threshold, with progressive increase in the limits of tolerance.^{208,209} In patients who cannot reach the ventilatory threshold during incremental testing, training can begin at a level closer to the maximum

intensity obtained.¹¹² Using the ventilatory threshold as a landmark when it is reached or knowing that it has not been reached during standardized testing facilitates higher-intensity targets and more efficient training.²⁰⁷

From a practical standpoint, a formal CPET study may not be necessary to build a tailored exercise program and others have used variables obtained in the 6MWT, such as peak heart rate,²¹⁰ to target exercise levels. Despite the expert opinions that CPET or 6MWT should be used to create individualized training programs, there are no data showing that the exercise prescription derived by these means improves quality of life or survival.

SAFETY CONSIDERATIONS AND CONTRAINDICATIONS TO CPET

Performing a CPET is not without risk, and the decision to conduct the test must reflect consideration of those risks relative to the benefits in terms of information gained. Multiple contemporary surveys indicate that the risks of complications that require hospitalization are low; the risk of serious arrhythmias, acute myocardial infarction, or sudden cardiac death during or immediately after an exercise test are less than 0.2%, 0.04%, and 0.01%, respectively.²¹¹ This estimate captures the risk for the entire population of individuals performing CPET and is likely to vary in a given patient on the basis of his or her underlying disease. Unfortunately, risk estimates are not available for every possible condition, and the clinician must use clinical judgment in assessing the risk and informing each individual.

Some diseases do carry significantly higher risks and represent absolute or relative contraindications to performing CPET (see Table 26-1). Patients with *implantable cardiac defibrillators* (ICDs) also require special attention. Documentation of the defibrillator settings should be reviewed before exercise to ensure that the peak heart rate during the test does not encroach on the rate at which the defibrillator is set to discharge. The defibrillator function should not be entirely disabled, however, as one needs maintain the ability to defibrillate patients who develop arrhythmias during the exercise test.

CONDUCTING EXERCISE TESTS

Exercise Equipment

A number of commercially available exercise monitoring systems allow breath-by-breath measurements of exhaled gases. The general components of these systems include an airflow transducer to measure the volumes of each inhalation and exhalation and rapid gas analyzers to measure the O₂ and CO₂ during inspiration and expiration. As technologies have improved, these components have become more reliable but still require strict and daily calibration tests to assure accurate data. Multiple resources are available with recommendations for calibration procedures and quality control.^{6,9,177} Gas exchange measurements during exercise should be reproducible, and therefore it is a good practice to have one or two individuals in the exercise laboratory perform monthly CPET to confirm that their data remain stable over time. Both maximal and submaximal tests can

be used for this purpose because reproducible data are generated in either case.

Exercise Modalities and Protocols

Cycle Ergometer versus Treadmill. Functional capacity is usually assessed in CPET by having the individual exercise on a stationary cycle ergometer or motorized treadmill. Either modality can be used to elicit progressively increasing work rates in subjects. Progressive work is produced on the cycle ergometer by increases in the resistance to pedaling. Through electronic braking and sensors, it is possible to gauge the work being done by the individual and quantify work over time as a rate in *watts* (W). Progressive work is produced on the treadmill by increases in the grade and speed of the treadmill. Because arm movement and the uplift of body weight while walking/running on the treadmill add to the work being performed, work on a treadmill is more dependent on an individual's weight and, as a result, is harder to quantify than with cycle ergometry, in which leg muscles do the vast majority of the work and the individual's weight is supported by the bicycle. Treadmill work is measured relative to each individual's resting energy expenditure and is typically expressed in terms of *metabolic equivalents* (METs). One MET represents the amount of oxygen consumed at rest and each successive stage achieved in a given treadmill protocol corresponds to a higher level of METs that can, in turn, be related to the individual's oxygen consumption (1 MET = 3.5 mL O₂/kg/min in the average adult).²¹² As discussed previously, oxygen consumption is also tightly linked with work rate on a cycle ergometer, with $\dot{V}O_2$ increasing at a rate of 10 mL/min/watt above the resting value. Hence watts and METs can be roughly compared through the shared $\dot{V}O_2$ and are dependent on the individual's weight. Table 26-4 provides examples of watts, oxygen consumption, and METs for two individuals of different weights to give the reader a general idea of how these measures of work compare.

Both exercise modalities can impose progressively increasing work rates that provide a range of oxygen consumptions to identify exercise patterns described earlier in this chapter. The resistance and, therefore, watts in cycle ergometry can be increased in either a continuous or stepwise manner over time. Treadmill work rates are usually increased according to specific protocols such as the

Table 26-4 Comparison of Oxygen Consumption and Metabolic Equivalents (METs) at Different Levels of Work in Individuals of Different Weights

Watts	70-kg PERSON		100-kg PERSON	
	$\dot{V}O_2$ (mL/min)	METs	$\dot{V}O_2$ (mL/min)	METs
0 (rest)	250	1.0	350	1.0
25	500	2.0	600	1.7
50	750	3.1	850	2.4
100	1250	5.1	1350	3.9
200	2250	9.2	2350	6.7
300	3250	13.3	3350	9.6
400	4250	17.3	4350	12.4

$\dot{V}O_2$ increases at a rate of 10 mL/min/watt above the resting value. One MET represents the amount of oxygen consumed at rest.

Bruce,²¹³ Balke,²¹⁴ or Naughton²¹⁵ that define how to change the speed and inclination of the treadmill over time. The work rate ramp or steps should be chosen so that subjects can perform 10 to 12 minutes of exercise before reaching their $\dot{V}O_{2\max}$, because this time frame usually provides the temporal resolution necessary to identify patterns of exercise responses. $\dot{V}O_{2\max}$ estimates tend to be 10% to 15% higher using a treadmill compared to a cycle ergometer due to the extra work being performed by the arms when walking or running. Each modality may offer advantages depending on the patient and goals of the test. Whereas cycle ergometry tends to be better for patients who are obese or have gait problems and is more suited for drawing arterial blood gases, treadmill testing may be preferred in patients whose symptoms are elicited with walking and running or in patients with exercise-activated pacemakers that sense arm movement.

Invasive Cardiopulmonary Exercise Testing. When competing comorbidities in a given patient make it difficult to determine the primary cause of exercise limitation, exercise with a right heart catheter can provide additional data to help (1) separate out the cardiac and pulmonary systems, (2) further differentiate the broad category of “cardiac limitation” as either right or left heart failure, and (3) identify a component of muscle deconditioning. The data available from the right heart catheter include mixed venous oxygen saturation and content, pulmonary artery pressure, pulmonary artery occlusion pressure, and thermomodulation cardiac output. With increasing exercise to exhaustion in a normal individual, cardiac output should increase fourfold to fivefold, but the mean pulmonary arterial pressure should remain less than 30 mm Hg.²¹⁶ In patients with left heart failure or pulmonary vascular disease, the mean pulmonary arterial pressure may increase above this level and, if associated with symptoms of dyspnea, may give a clue to underlying mechanisms. Pulmonary vascular resistance can be calculated to determine if elevated pulmonary artery pressures are due to left-sided heart failure or pulmonary vascular disease. Because intrathoracic pressure affects right-heart catheterization measurements, the pulmonary artery occlusion pressure must be measured at end-exhalation, which may be difficult to achieve without asking patients to temporarily alter their breathing patterns during measurements. Stroke volume can be calculated from the heart rate and cardiac output rather than assessed through a surrogate measure, the O_2 pulse. Placement of an arterial line with the right heart catheter allows calculation of cardiac output using the Fick equation and determination of the arteriovenous oxygen content difference, with narrow values of the latter providing evidence of deconditioning as a cause of exercise limitation.

Noninvasive Estimates of Cardiac Output during CPET. A number of noninvasive commercial methods are also available for estimating the cardiac output during exercise. They rely on a variety of different technologies, including CO_2 rebreathing,²¹⁷ pulse contour analysis,²¹⁸ chest bioreactance,²¹⁹ echocardiography,²²⁰ and inert gas rebreathing.²²¹ The technology that has been most rigorously evaluated in exercise²²² is the inert gas rebreathing

method. Although the available evidence indicates that these measurements are feasible and that cardiac output and $\dot{V}O_2$ are tightly correlated in both normal subjects and individuals with heart failure,²²³ their clinical utility remains unclear.²²¹

Indications for Arterial Blood Gases

Arterial blood gases provide additional data that assist in differentiating the causes of exercise limitation and dyspnea. In particular, they allow the determination of the (1) (A-a) PO_2 to evaluate gas exchange; (2) arterial PCO_2 as the gold standard for identifying ventilatory limitation; (3) V_D/V_T as an indicator of pulmonary vascular disease; and (4) base deficit as a surrogate for lactic acidosis. Arterial blood gases can be measured either once immediately following conclusion of the exercise test or at repeated intervals through the test. Both sampling methods permit determination of the dead space fraction at end-exercise while the latter method also allows one to roughly estimate the position of the ventilatory threshold. The latter approach requires an arterial line while a single needle puncture can be used for the former. The operator should be aware that arterial puncture following maximal exertion can cause a vagal reaction and hypotension, especially in younger subjects.

INTERPRETING CARDIOPULMONARY EXERCISE TESTS

In [Figure 26-9](#), a basic approach is shown for interpreting the results of cardiopulmonary exercise tests. Because CPET interpretation is highly dependent on data quality, the reader should first ensure that there are no systematic data collection errors and that the patient gave a full effort. Several key aspects of the interpretation process are considered as follows.

Identifying the Ventilatory Threshold

One of the critical steps in CPET interpretation is identifying whether the patient reached a ventilatory threshold, because it is one of the primary means of distinguishing between cardiac or pulmonary vascular limitation, on the one hand, and ventilatory limitation, on the other. As indicated earlier, there are actually two distinct ventilatory thresholds but, for the majority of CPET interpretations, it is less important to identify the specific threshold and more important to identify whether the range of expected responses is consistent with either threshold.

The ventilatory threshold can be identified by invasive and noninvasive means. The former involves measurement of arterial lactate or bicarbonate concentrations. A single measurement at end-exercise is sufficient for a binary decision as to whether the threshold was reached, whereas serial measurements every other minute during exercise can be used as part of several different techniques to determine the $\dot{V}O_2$ at which the threshold was reached.^{13,224} Several noninvasive methods can also be used, including the V-slope method described earlier (see [Fig. 26-1](#)), identification of the point at which $\dot{V}E/\dot{V}O_2$ and $\dot{V}E/\dot{V}CO_2$ reach their nadir and begin to increase, or identification of the point at which the $PETO_2$ starts to rise or $PETCO_2$ starts to decrease ([Fig. 26-10](#)). The accuracy of the different methods varies on the basis of operator experience, the testing

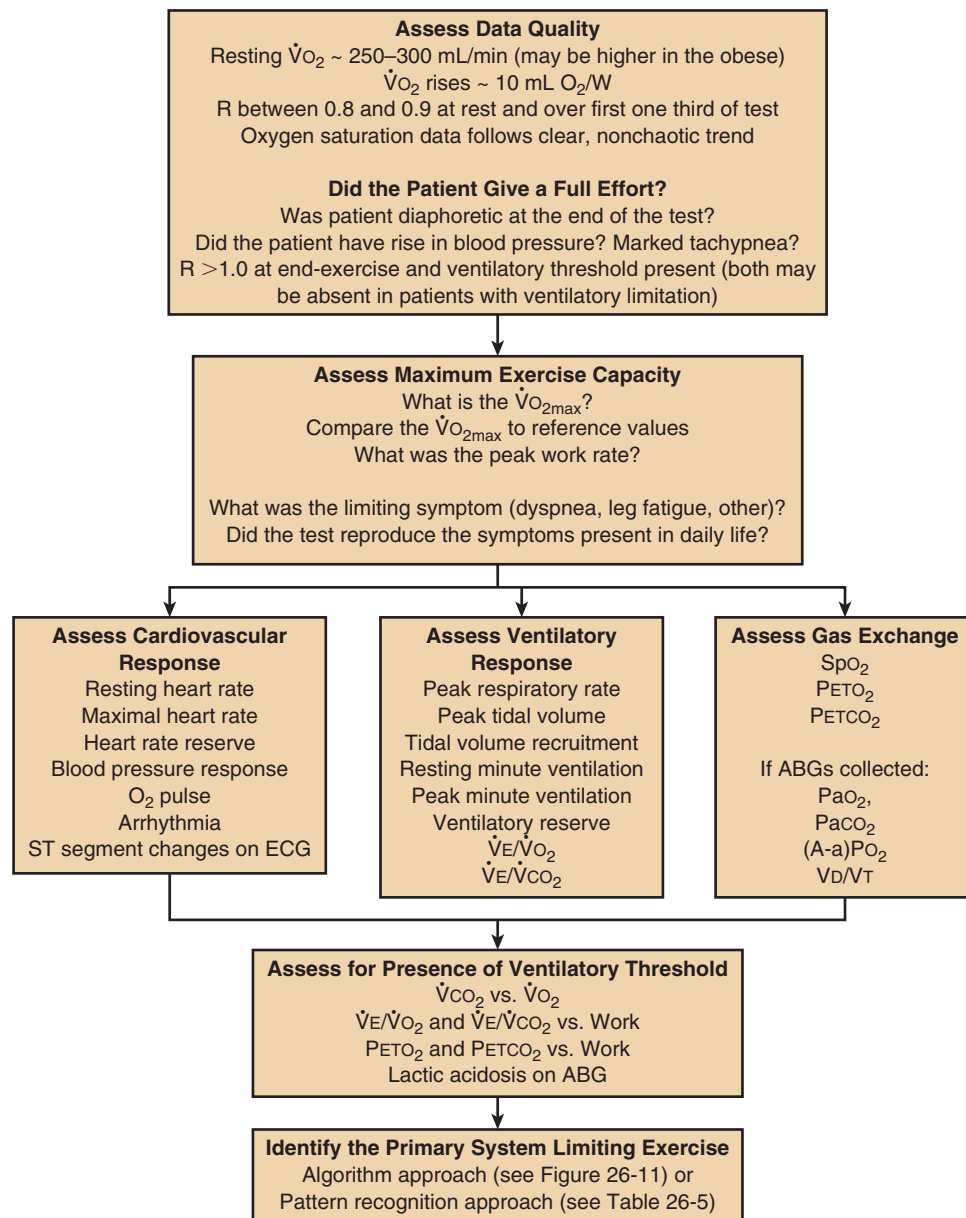

Figure 26-9 A general approach to cardiopulmonary exercise test interpretation. Because data interpretation is highly dependent on the quality of the data, the initial steps involve ensuring there are no systematic data errors and that the patient gave a complete effort. Once this is done, the next tasks are to assess maximum exercise capacity and the cardiovascular, ventilatory, and gas exchange responses and then identify whether a ventilatory threshold is present and determine the primary system limiting exercise. ABG, arterial blood gas; ECG, electrocardiogram; R, respiratory exchange ratio; SpO_2 , oxygen saturation by pulse oximetry; W, watt.

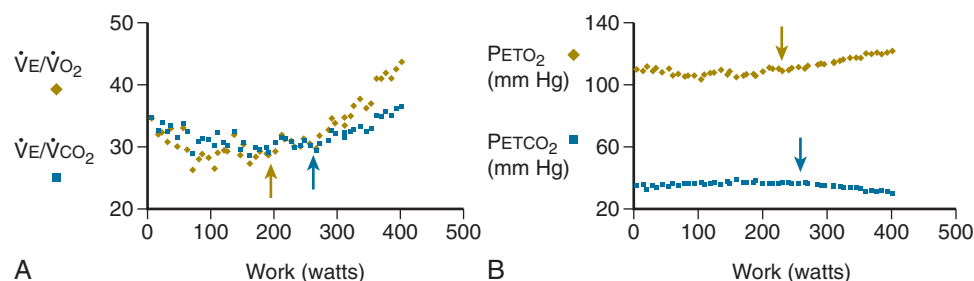

Figure 26-10 A, Analysis of ventilatory equivalents to identify whether a ventilatory threshold is present. Following the increase in minute ventilation at the ventilatory threshold, ventilatory equivalents for oxygen ($\dot{V}_E/\dot{V}O_2$, denoted in brown) and carbon dioxide ($\dot{V}_E/\dot{V}CO_2$, denoted in blue) begin a steady rise. The point at which each variable starts to rise is marked by an arrow in the respective colors. The start of the rise in $\dot{V}_E/\dot{V}O_2$ is associated with the first ventilatory threshold and is expected to take place before the rise in $\dot{V}_E/\dot{V}CO_2$. **B**, Using changes in end-tidal partial pressure of oxygen ($PETO_2$) and carbon dioxide ($PETCO_2$) to identify whether a ventilatory threshold is present. At the ventilatory threshold, minute ventilation (\dot{V}_E) increases out of proportion to the changes in oxygen consumption ($\dot{V}O_2$) and carbon dioxide production ($\dot{V}CO_2$). As a result, $PETO_2$ (denoted in brown) begins a steady rise (brown arrow), while $PETCO_2$ (denoted in blue) begins a steady decrease (blue arrow).

protocol, and the data collection system,⁶ and there is no evidence that any particular noninvasive method is superior to the others.^{225,226} This is not a critical issue in most CPET interpretations because the key question is whether or not the threshold is reached rather than when it is reached. When the specific $\dot{V}O_2$ at the ventilatory threshold must be known, as in devising exercise prescriptions or training protocols, the key factor will be application of a consistent approach from test to test.

Identifying the Primary System Limiting Exercise: Algorithmic versus Pattern Recognition Approaches

Perhaps the most important aspect of CPET interpretation is identifying the primary reason for exercise limitation. One approach to this task, first introduced by Wasserman

and colleagues,²⁸ employs a binary tree algorithm and flow charts that direct the interpretation through a series of decision points to specific causes of exercise limitation. A simplified flow chart is shown in Figure 26-11 to demonstrate the concept. The advantages of this approach are that the decision points and values are well defined so that there is no ambiguity in the direction to branch in the flow chart. This strategy is probably easier to follow for the novice interpreter than the pattern recognition approach outlined later. The primary disadvantage is that the interpretation is entirely dependent on a single data point at each bifurcation. Any error in data collection or misinterpretation at one bifurcation can direct the interpretation down a wrong pathway and an incorrect diagnosis. A secondary disadvantage is that CPET interpretation by this method requires an extensive array of flow charts.

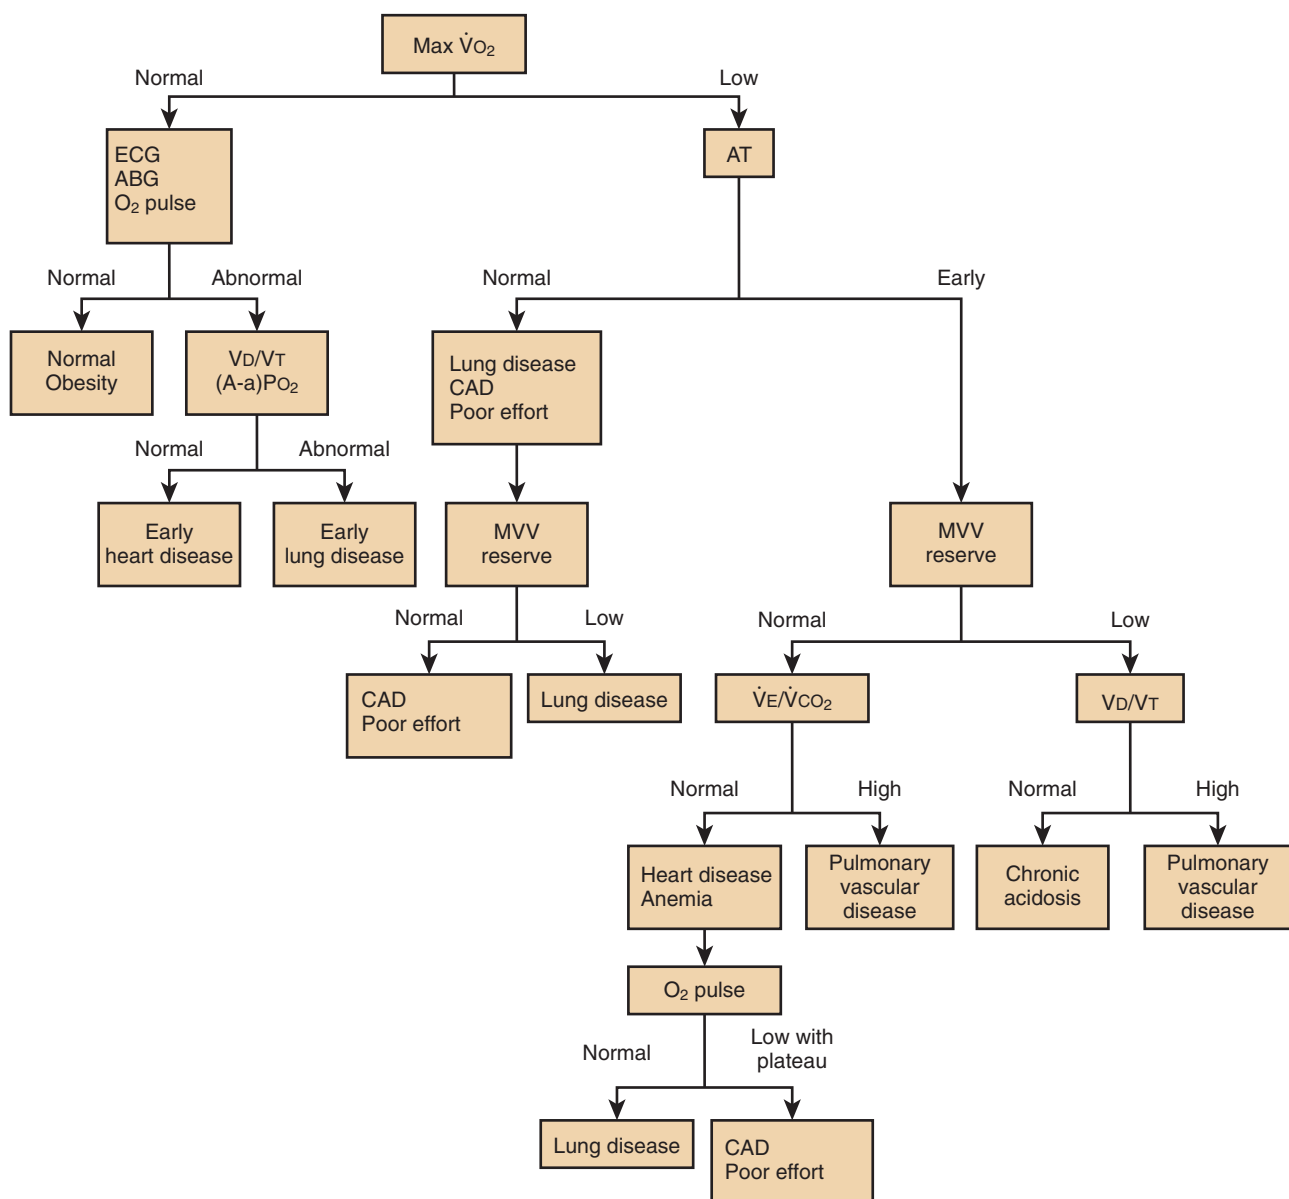

Figure 26-11 Simplified flow chart demonstrating decision making in cardiopulmonary exercise test interpretation. The decision tree begins at the top with the maximum oxygen consumption ($\dot{V}O_{2max}$) compared with predicted values. ABG, arterial blood gas; AT, anaerobic threshold; CAD, coronary artery disease; ECG, electrocardiogram; MVV, maximum voluntary ventilation; (A-a)PO₂, alveolar-arterial oxygen difference; V_D/V_T, dead space fraction; $\dot{V}E/\dot{V}CO_2$, ventilatory equivalents for carbon dioxide. (Modified from Wasserman K, Hansen JE, Sue DY, et al: Principles of exercise testing and interpretation, ed 5. Philadelphia, 2012, Lippincott Williams & Wilkins.)

Table 26-5 Identifying the Pattern of Limitation on Cardiopulmonary Exercise Testing

Observation	PATTERN OF LIMITATION		
	Cardiac	Pulmonary Vascular and Interstitial Lung Disease*	Ventilatory
Clear ventilatory threshold	⊙	⊙	
Plateau in O ₂ pulse late in exercise	⊙	⊙	⊙ [†]
High \dot{V}_E/\dot{V}_{CO_2}	⊙	⊙	
High \dot{V}_E/\dot{V}_{O_2}	⊙	⊙	
\dot{V}_{Emax} far below maximum voluntary ventilation (MVV)	⊙		
Metabolic acidosis by arterial blood gas late in exercise	⊙	⊙	
Decreasing PETCO ₂ late in exercise	⊙	⊙	
R clearly rises above 1.0	⊙	⊙	
Stop exercising due to leg fatigue	⊙	⊙	
Heart rate near predicted maximum late in exercise	⊙		
ST changes on electrocardiography	⊙		
Inappropriate blood pressure response	⊙		
Increasing or unchanged VD/VT by arterial blood gas late in exercise		⊙	
Absent ventilatory threshold			⊙
Decrease in oxygen saturation		⊙	⊙
Heart rate far below predicted maximum late in exercise			⊙
Increasing or unchanged PETCO ₂ late in exercise			⊙
PaCO ₂ > 40 mm Hg by arterial blood gas (end-exercise)			⊙
\dot{V}_{Emax} near MVV			⊙
Decreasing tidal volume			⊙
R does not increase above 1.0			⊙
Stop exercising due to dyspnea			⊙

*Pulmonary vascular and interstitial lung diseases share many common features on CPET, and additional resting, such as echocardiography, pulmonary function testing, and imaging, is often necessary to distinguish between the two forms of disease.

[†]Can be seen if “air trapping” affects cardiac function.

The size of the marker indicates the relative importance of the observation.

An alternative method is one of pattern recognition that uses the expected trends for multiple variables over the course of progressive exercise to identify the organ system limiting exercise. As discussed earlier, general disease categories such as heart failure, pulmonary vascular disease, or ventilatory insufficiency have expected patterns of exercise responses (Table 26-5). These patterns can be weighted by their relative specificity for each organ system and then examined in sum to suggest the most likely organ system limiting exercise. Patients with cardiac limitation, for example, will demonstrate a ventilatory threshold, a decreased PETCO₂ and arterial PCO₂, and an increased ventilatory \dot{V}_E/\dot{V}_{O_2} and \dot{V}_E/\dot{V}_{CO_2} at end-exercise. Patients with pulmonary hypertension demonstrate many similar findings but will manifest hypoxemia and a fixed VD/VT in late exercise. Other temporal trends that are specific for an organ system failure can be seen with exercise but not regularly enough to warrant listing in Table 26-5. Patients with severe heart failure, for example, may have exercise oscillatory ventilation^{64,65} that can be readily seen when the \dot{V}_E is plotted as a function of time or work rate.

Because the various observations listed in Table 26-5 are not necessarily present in every patient, a useful approach in the pattern recognition method is to conceptualize it as a scale on which the different observations are blocks that

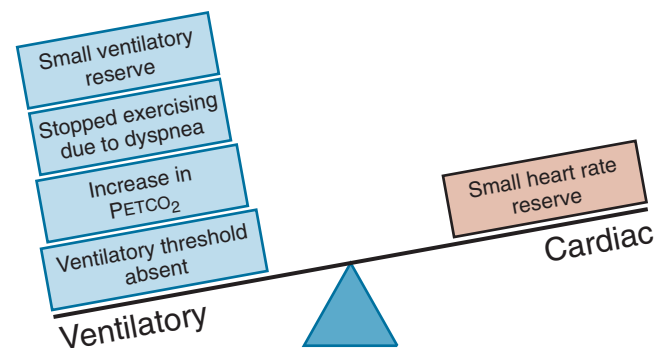

Figure 26-12 The “balance” approach to identifying the pattern of exercise limitation. In this example, the patient has many features consistent with ventilatory limitation due to COPD and only one aspect of the data consistent with a cardiac limitation. Because the preponderance of data favors the left side of the balance, this patient would be best labeled as having a ventilatory limitation pattern.

are placed on the side of the scale representing the potential limiting pattern (Fig. 26-12). Each block may be of different size representing the relative weight placed on that particular factor. The presence or absence of a ventilatory threshold would be the biggest block in this method. The side of the scale with the greatest weight (number of blocks)

is most likely to be the limiting organ system. By being less dependent on single parameters to make a decision throughout a binary tree, pattern recognition may be less prone to misclassifications of the limiting organ system. The disadvantage of the pattern recognition approach is that it requires some expertise to recognize the patterns.

Each of these approaches to data interpretation has strengths and weaknesses, and neither has been demonstrated to be superior to the other. Regardless of the interpretation method used, the CPET data are more useful for determining the primary system limiting exercise and less effective at identifying the specific disease process at work.

ALTERNATIVE METHODS OF ASSESSING EXERCISE PERFORMANCE

In addition to the symptom-limited progressive work exercise test, there are several other means for assessing exercise responses in clinical practice.

The 6-Minute Walk and Shuttle Walk Tests

The 6MWT is a widely available, inexpensive, and reproducible submaximal exercise test during which subjects walk back and forth along a flat indoor course varying in length between 30 and 100 m for a period of 6 minutes under the supervision of a trained technician following a specified testing protocol.²²⁷ Individuals move at their own pace, can use supplemental oxygen, and, unlike in a cardiopulmonary exercise test, may stop to rest if necessary. The primary measurements obtained during the test include the distance walked, as well as heart rate, oxygen saturation, blood pressure, and subjective ratings of dyspnea and leg fatigue. The test is usually performed only once during a given testing period, although some have argued that addition of a second trial improves the yield of the study.²²⁸

The 6MWT is used for two general purposes. The first of these is to monitor response to interventions or follow disease activity over time as demonstrated by the extensive use of the distance walked as an outcome in pulmonary hypertension²²⁹ and idiopathic pulmonary fibrosis trials,²³⁰ while the other is to assess patient prognosis. Studies done in patients with COPD,²³¹ pulmonary hypertension,²³² and idiopathic pulmonary fibrosis^{233,234} have shown relationships between the distance walked or development of hypoxemia during the test and outcomes such as mortality risk. Such information can be used to guide management decisions, such as when to list a patient for transplantation. Whether the distance walked is an adequate surrogate for $\dot{V}O_{2\max}$ remains unclear, however, because studies have reported varying degrees of correlation between these two variables.²³⁵ Importantly, due to the limited nature of the data available from the test, the 6MWT cannot be used to determine the etiology of exercise limitation. In addition, it is generally only relevant to patients or elderly individuals who are unable to maintain a normal or brisk walking pace and has little role in the assessment of exercise responses in fit individuals.

Use of the test for the purposes noted earlier requires recognition of several important issues. First, although reference values for normal individuals have been published,^{236,237} their utility is limited by the fact that test results vary on the basis of differences in testing methodology and the popula-

tion under consideration. Second, subject performance can be affected by learning, verbal encouragement, and course layout, necessitating strict adherence to published guidelines for conducting the test.²²⁷ Finally, when using the 6MWT to assess response to therapy or change over time, clinicians must understand the minimal clinically important difference, the threshold at which a change in 6MWT is recognized as either important by the patient or associated with other outcomes. Minimal clinically important difference values have been published but vary depending on the patient population and outcome in question.^{238,239}

The incremental *Shuttle Walk Test* (SWT) is a less widely used alternative to the 6MWT, which requires the patient to walk at a specified pace that increases over time until the individual can no longer maintain the pace or stops due to symptoms. Designed as a less invasive assessment of maximum exercise capacity, the test correlates reasonably well with $\dot{V}O_{2\max}$ ²⁴⁰ and can be used to monitor responses to therapeutic interventions.²⁴¹ Reference values for normal individuals are lacking, and its use is largely limited to following changes over time in a given patient or to making comparisons between patient groups.

More thorough reviews of the clinical utility and limitations of these tests are available elsewhere.^{242,243}

Exercise Treadmill Testing

In addition to its role in cardiopulmonary testing described earlier, *exercise treadmill testing* (ETT) is also commonly performed without exhaled gas collection. Because data collection is limited in such cases to assessment of symptoms, blood pressure, heart rate, oxygen saturation, electrocardiography, and exercise duration, ETT cannot be used to determine which system is limiting exercise but does provide information for assessing exercise responses and guiding management.

The primary use of ETT is to identify coronary artery disease in low- to intermediate-risk individuals capable of exercise who have normal baseline electrocardiograms (absence of left bundle branch block, left ventricular hypertrophy with any repolarization abnormalities, or ST segment depression). The test can be performed in the outpatient setting, as well as part of diagnostic protocols for low-risk patients admitted to chest pain units from the emergency department.²⁴⁴ Myocardial perfusion imaging is combined with ETT for patients with abnormal baseline electrocardiograms and is often necessary when evaluating female patients because the predictive capability of routine ETT is limited by the lower pretest probability of *coronary artery disease* (CAD) in this patient group.²⁴⁵

Using the concept of *metabolic equivalents* (METs) rather than direct measurement of $\dot{V}O_{2\max}$, ETT can also be used to assess exercise capacity. Although this approach is less precise than measurements using exhaled gas collection, various studies have demonstrated its utility in patient assessment and prognostication. Higher exercise capacity on ETT is associated with less significant coronary artery disease on left heart catheterization, for example,²⁴⁶ while decrements in exercise capacity measured by ETT predict mortality in both men and women.^{157,158} Consideration of exercise capacity may also improve the predictive ability of risk models on the basis of traditional clinical CAD risk factors.²⁴⁷

Other variables measured during ETT can also be related to mortality risk or the severity of coronary artery disease. For example, decreased heart rate recovery following exercise (<25 beats/min) is associated with increased risk of sudden death from myocardial infarction,²⁴⁸ whereas impaired heart rate response to increasing work rates is an independent predictor of mortality in asymptomatic women²⁴⁹ and impaired blood pressure responses are useful for identifying patients with three-vessel coronary disease.²⁵⁰ More complete reviews of the utility of ETT can be found elsewhere.^{251,252}

Key Points

- The ability to perform sustained exercise requires tight integration of multiple systems. Disease within any of these systems can manifest as dyspnea during exertion or as exercise limitation.
- Assessment of maximal oxygen consumption provides valuable insight into maximum exercise capacity, as well as important aspects of cardiac function including cardiac output and stroke volume.
- Normal individuals demonstrate a characteristic pattern of responses to progressive exercise to a symptom-limited maximum. Characteristic patterns of deviation from these normal responses are seen in various disease states such as heart failure, pulmonary vascular disease, interstitial lung disease, and COPD.
- Cardiopulmonary exercise testing can be used to characterize the pattern of responses to progressive exercise and to identify the primary organ system limiting exercise capacity.

- Beyond assessing exercise capacity, cardiopulmonary exercise testing can be used to gather prognostic information and guide management in certain patient groups, guide perioperative management in thoracic and other major surgical procedures, assess disability, and develop exercise prescriptions as part of rehabilitation programs.

Risk Modifications

INTRODUCTION

Patients undergoing thoracic surgeries are different from those undergoing most noncardiac surgeries. Although the risk for perioperative major cardiac complications is significant, *postoperative pulmonary complications* (PPCs) contribute equally, if not more, to perioperative morbidity and mortality in this group of patients. Almost by definition, lung resection leaves patients with impaired pulmonary function (with some important exceptions, see later). The purpose of preoperative assessment of thoracic surgery patients is to identify high-risk patients (including those in whom the risk may preclude surgery), to plan the intraoperative and postoperative management, and to treat concomitant medical issues, with the goal of optimizing patient outcomes.

In this chapter we will provide an approach to the preoperative evaluation of patients undergoing thoracic surgery in light of the most recent evidence about the physiologic demands that these surgeries impose on patients. We will also briefly touch upon important issues during the intraoperative and immediate postoperative period that may influence outcome and may be of interest to pulmonologists who are involved in managing this interesting and challenging group of patients.

DEFINITION AND IMPACT OF POSTOPERATIVE PULMONARY COMPLICATIONS IN THORACIC SURGERY

Unsurprisingly, postthoracic surgery patients have a higher risk for PPCs (Table 27-1) than patients having upper or lower abdominal surgeries (19% to 59% compared to 16% to 17% and 0% to 5%, respectively¹).

One reason for the wide variability in the reported incidence of PPCs is the variability in defining what constitutes a PPC. For the purposes of this chapter we will define PPCs as shown in Table 27-1. PPCs after lung resection are a major cause or contributing factor to postoperative deaths, accounting for up to 84% of all deaths.¹ PPCs have a disproportionate impact on hospital costs as well,

with one study finding that PPCs (defined by the authors as pneumonia, unplanned intubation, and failure to wean from mechanical ventilation) added more to hospital costs than either cardiovascular, infectious, or thromboembolic complications.² An important study using data from the prospectively collected National Surgical Quality Improvement Program showed that a postoperative complication within the first 30 days after eight common surgeries (including lung resection) was independently associated with increased short-term (30-day) and long-term (1- and 5-year) mortality.³ Compared to wound complications, the other most common postoperative complication, PPCs had a disproportionate adverse impact on survival, as shown in Figure 27-1.

MORTALITY AND MORBIDITY IN THORACIC SURGERY: CAN WE IDENTIFY PATIENTS AT THE HIGHEST RISK FOR ADVERSE OUTCOMES?

Lung cancer is the most common indication for lung resection in the Western world,⁴ and, for patients with localized cancer, lung resection provides the best chance of a cure.⁵ The poor outcomes associated with nonoperative management of lung cancer together with improvements in surgical technique, anesthetic management, and postoperative management have resulted in larger numbers of sicker patients being offered surgery. It is now well established that the operative volume of the hospital where lung resection is performed has an important impact on outcomes.⁶⁻⁸ Mortality has also been reported to be lower when surgeries are performed by board-certified thoracic surgeons compared to nonspecialists, even though the board-certified thoracic surgeons often operate on patients with a higher burden of comorbid disease.⁹

Consequently, there is significant interest in the ability of clinicians to be able to predict the risk for mortality and major morbidity following thoracic surgery, both to ensure quality and to provide patients with a reasonable estimate of the risk involved before undertaking surgery.¹⁰ Currently available tools are limited in their utility by the quality of the databases that are used to generate them.

Figure 27-1 Postoperative pulmonary complications (PPCs) have a significant influence on long-term mortality. Cox survival curves of study patients stratified as to whether or not the patients had sustained a PPC (*left*) or wound complication (*right*) in the first 30 postoperative days. Compared to wound complications, pulmonary complications had a disproportionate impact on survival. (From Khuri SF, Henderson WG, DePalma RG, et al: Determinants of long-term survival after major surgery and the adverse effect of postoperative complications. *Ann Surg* 242[3]:326–341; discussion 341–343, 2005.)

Table 27-1 Definition of Postoperative Pulmonary Complications

1. Nosocomial pneumonia (bacteriologically confirmed)
2. Lobar or whole lung atelectasis on chest radiograph
3. Acute respiratory failure: mechanical ventilation for > 24 hr OR reintubation
4. Prolonged air leak requiring > 7 days of chest tube drainage
5. Pulmonary embolism (confirmed radiographically or on autopsy)
6. Acute respiratory distress syndrome
7. Pneumothorax
8. Bronchospasm
9. Aspiration pneumonitis

From Stephas F, Boucheseiche S, Hollande J, et al: Pulmonary complications following lung resection: a comprehensive analysis of incidence and possible risk factors, *Chest* 118:1263–1270, 2000.

The Thoracoscore was developed in France using data obtained from more than 15,000 patients who were enrolled in a nationally representative thoracic surgery database (Epithor, developed by the French Society of Thoracic and Cardiovascular Surgery). The authors identified nine factors that predicted increased mortality: age, sex, dyspnea score, American Society of Anesthesiologists status, performance status, priority of surgery, diagnosis, procedure class, and comorbid disease.¹¹ The model was subsequently validated in the United States¹² and incorporated into the British Thoracic Society guidelines for risk assessment of patients with lung cancer¹³; it is available in a Web-based calculator (http://sfctcv.fr/pages/epithor/thoracoscore_engl.php). However, more recent studies have found the Thoracoscore to have a lower predictive power than reported earlier.^{14,15} Recently Kozower and colleagues¹⁶ reported on a model of perioperative risk for mortality and major morbidity from a

database of more than 18,000 patients—the *Society of Thoracic Surgeons* (STS) General Thoracic Database. They found 12 risk factors to be associated with mortality, including American Society of Anesthesiologists status, the Zubrod functional status scale, renal dysfunction, induction chemotherapy, *forced expiratory volume in the first second* (FEV₁), body mass index (an increase was protective), male sex, and importantly, the type of surgery (pneumonectomy and bilobectomy had significantly higher mortality risks).¹⁶ An important limitation of both the Thoracoscore and the STS models is the lack of incorporation of *diffusing capacity for carbon monoxide* (DL_{CO}) data into their models because the majority of the patients in this database did not have measurement of diffusion capacity. In a subset of the STS database patients that did have DL_{CO} values (almost 7900 patients), DL_{CO} was found to be a strong independent predictor of mortality, in addition to the factors mentioned previously.¹⁷ Although these and other predictive models are still far from ideal, they do provide the clinician with objective data that may help supplement individual judgment in planning the best course of action for complex patients.

ASSESSMENT OF CARDIAC RISK IN PATIENTS WITH LUNG DISEASE

Patients with lung cancer often have cardiovascular disease, because cigarette smoking is a shared risk factor for both diseases. The revised guidelines from the *American College of Cardiology and the American Heart Association* (ACC/AHA) are particularly helpful in evaluating cardiac risk¹⁸ (Fig. 27-2).

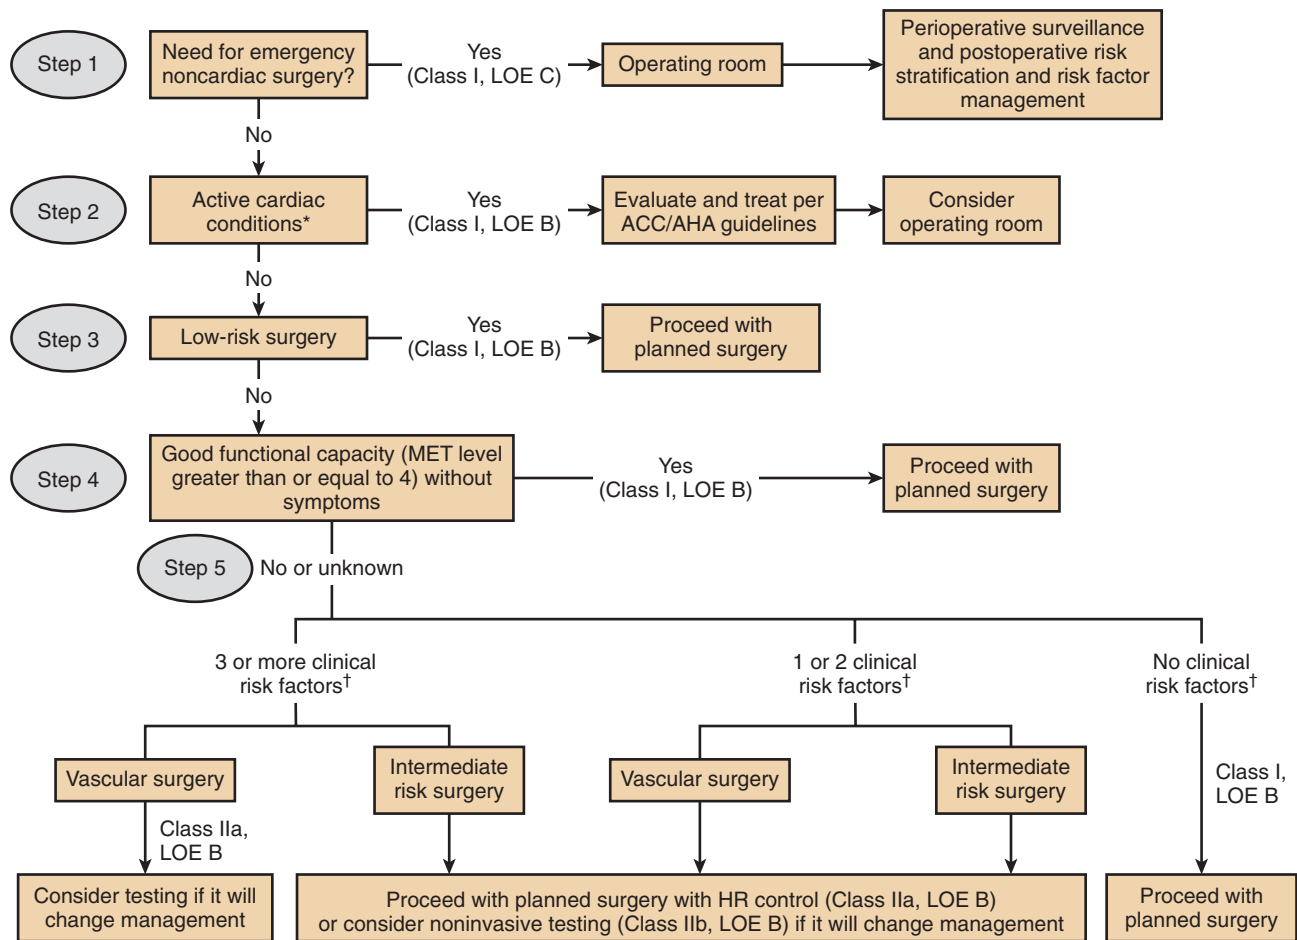

Figure 27-2 Cardiac evaluation and care algorithm for noncardiac surgery based on active clinical conditions, known cardiovascular disease, or cardiac risk factors for patients 50 years of age or greater. *Active cardiac conditions include unstable coronary syndromes, decompensated heart failure, significant arrhythmias, and severe valvular disease. †Clinical risk factors include ischemic heart disease, compensated or prior heart failure, diabetes mellitus, renal insufficiency, and cerebrovascular disease. ACC, American College of Cardiology; AHA, American Heart Association; LOE, level of evidence; MET, metabolic equivalent; HR, heart rate. (From Fleisher LA, Beckman JA, Brown KA, et al: ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery. *Circulation* 116[17]:e418–e499, 2007.)

The pathway for both emergent and elective surgeries in patients with active cardiac conditions (a *myocardial infarction* [MI] < 30 days ago, unstable angina, decompensated heart failure, significant arrhythmias, or severe valvular disease) is relatively straightforward. Most thoracic procedures fall into the intermediate risk category (with a combined risk for cardiac death and nonfatal MI between 1% and 5%), and will need a cardiac workup if they have *both* a poor functional capacity—defined as an exercise capacity of less than 4 metabolic equivalents (METs; 1 MET is approximately the level of effort required to climb up a flight of stairs) *and* more than one risk factor on the Revised Cardiac Risk Index¹⁹ (comprising a history of ischemic heart disease, cerebrovascular disease, heart failure, diabetes mellitus, and renal insufficiency). Most thoracic surgery patients in this group are likely to benefit from perioperative heart rate control. The ACC/AHA guidelines recommend noninvasive stress testing in this group of patients only if it is likely to change clinical management. Some patients may fall into relatively ill-defined areas in the guidelines, and they benefit from the opinion of an experienced cardiologist. A few specific situations are examined in the following section.

INDICATIONS FOR CORONARY REVASCULARIZATION

There has been a consensus over the last decade that invasive testing and coronary revascularization (either with bypass surgery or percutaneous coronary intervention) are unlikely to improve outcomes in noncardiac surgery unless the intervention is independently indicated for an acute coronary syndrome. In the Coronary Artery Revascularization Prophylaxis trial for patients undergoing vascular procedures, McFalls and associates²⁰ randomly assigned 510 patients with significant coronary artery stenosis from among 5859 patients to either coronary artery revascularization or no revascularization before surgery. The short-term risk for death or MI or long-term outcomes was similar in both groups. It is important to remember that the study excluded patients with more than 50% left main vessel disease, a left ventricular ejection fraction of less than 20%, and severe aortic stenosis.²⁰ Subsequent studies have supported these conclusions.^{21,22} (These studies were performed in the vascular surgery population, because this group of patients is at the highest risk for perioperative cardiac death/nonfatal MI.¹⁸) Although prospective data in

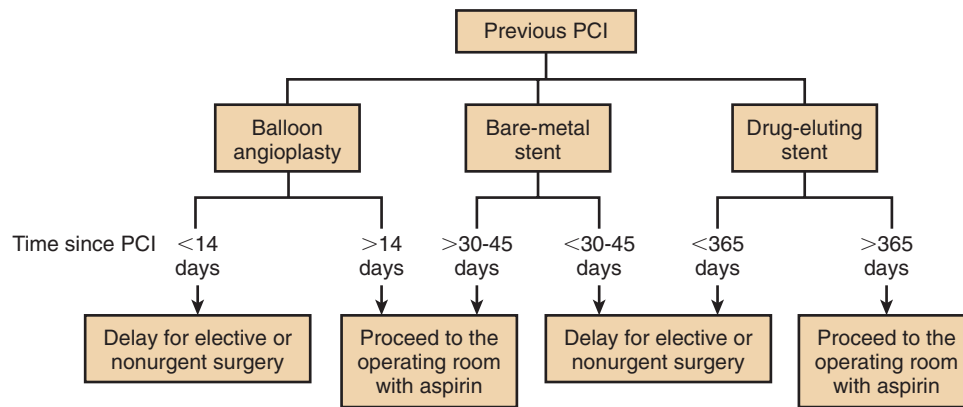

Figure 27-3 Proposed approach to the management of patients with previous percutaneous coronary intervention (PCI) who require noncardiac surgery, based on expert opinion. (From Fleisher LA, Beckman JA, Brown KA, et al: ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Writing Committee to Revise the 2002 Guidelines on Perioperative Cardiovascular Evaluation for Noncardiac Surgery]: developed in collaboration with the American Society of Echocardiography, American Society of Nuclear Cardiology, Heart Rhythm Society, Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, Society for Vascular Medicine and Biology, and Society for Vascular Surgery. *Circulation* 116[17]:e418-e499, 2007.)

thoracic surgery patients are lacking, it is not unreasonable to extrapolate these data to the thoracic surgery population. A number of retrospective studies show a higher incidence of major cardiac adverse events in patients who undergo lung surgery after the placement of either a bare metal stent or a drug-eluting stent.²³⁻²⁵ The difficult problem of a patient who needs both coronary revascularization and lung resection for cancer is best resolved on a case-by-case basis. The ACC/AHA recommended approach to nonemergent surgery in patients who have had a percutaneous coronary intervention is laid out in Figure 27-3.

β-BLOCKADE

The publication of the POISE (*PeriOperative ISchemic Evaluation*) trial in 2008 resulted in significant changes to the ACC/AHA recommendations on perioperative β-blockade that were laid out in the 2009 focused update on perioperative β-blockade.²⁶ The POISE investigators randomized 8351 patients with or at risk for atherosclerotic disease to a fixed, relatively high dose of extended-release metoprolol (200 mg/day) compared to placebo, beginning with 100 mg 2 to 4 hours before surgery and continuing for 30 days. Fewer patients in the metoprolol group had an MI. However, more patients died in the metoprolol group than in the placebo group. These deaths were attributed to a higher incidence of strokes in the metoprolol group, perhaps secondary to a higher incidence of hypotension and bradycardia in these patients.²⁷ The POISE study therefore raised the possibility that initiating β-blockers perioperatively in β-blocker-naïve patients *without titrating the dose to heart rate and blood pressure parameters* may be associated with worse outcomes. Consequently, although continuing β-blockers for patients who are already on these medications remains a class I recommendation, the ACC/AHA has downgraded its recommendation for initiating β-blockers in high-risk vascular surgery patients from class I to class IIa and added the proviso that β-blockers should be titrated to heart rate and blood pressure. A similar recommendation applies to high-risk thoracic surgical patients. A new recommendation has been added advising against the initiation of high-

dose β-blockers in the absence of titration (class III).²⁶ Another issue with perioperative β-blockade is that clinicians are sometimes reluctant to use these drugs on elderly patients and in patients with *chronic obstructive pulmonary disease* (COPD) for fear of exacerbating airway obstruction. However, the data suggest that, not only is it safe to administer β-blockers to such patients, but that failing to use these drugs may be associated with worse outcomes.²⁸⁻³⁰

ATRIAL FIBRILLATION PROPHYLAXIS

Atrial fibrillation (AF), the most common arrhythmia following general thoracic surgical procedures, develops in 12% to 44% of patients after lung resection and esophageal surgeries.^{31,32} Patients with postoperative AF have increased lengths of hospital stay, increased medical costs, and increased risks for stroke, cognitive dysfunction, and death.^{31,33} Consequently, effective prophylaxis to prevent postoperative AF is an important goal. The recommendations in this section are derived from clinical practice guidelines on AF prophylaxis by the STS.³⁴ As in the ACC/AHA guidelines regarding perioperative β-blockade, it is important to continue β-blockers in patients already taking them to reduce the risk for β-blocker withdrawal. The data here come chiefly from the cardiac surgery literature, where propranolol withdrawal has been associated with new-onset AF.^{35,36} The dose of β-blockers in these patients should be adjusted, and “hold-parameters” should be in place because many of them are likely to have epidural catheters in place for analgesia, increasing the risk for hypotension and bradycardia. In patients not taking β-blockers preoperatively and who do not need to be started on them based on the ACC/AHA recommendations described earlier, calcium channel blockers such as diltiazem have proven to be effective at AF prophylaxis.^{37,38} Amiodarone is effective at AF prophylaxis^{39,40}; however, in one study, amiodarone was associated with an increase in the incidence of acute respiratory distress syndrome—particularly if given after a pneumonectomy.³⁹ The use of amiodarone may also be associated with a higher incidence of postoperative acute respiratory distress syndrome^{41,42} and, if there is

preexisting pulmonary disease, a higher risk for amiodarone-induced pulmonary toxicity.⁴³ On the other hand, two more recent studies by Tisdale and coworkers in patients after pulmonary resection⁴⁰ and after esophagectomy⁴⁴ did not find increased pulmonary toxicity with amiodarone, although the doses used were lower. For the present the STS recommends the use of amiodarone only in very limited circumstances and in carefully controlled doses. It recommends against the use of amiodarone for AF prophylaxis in patients undergoing pneumonectomy. Digitalis and flecainide should not be used for the prophylaxis of AF.^{37,45} Therefore the current recommendations for AF prophylaxis are to continue β -blockade throughout the perioperative period if the patient is already taking β -blockers. If the patient is not taking them, then calcium channel blockers would be recommended for prophylaxis.

SPECIAL PATIENT POPULATIONS

PATIENTS WHO SMOKE

Smoking is one of the most important causes of preventable death in the world. Studies suggest that smoking is responsible for almost half a million deaths and more than \$200 billion in health care costs and lost productivity in the United States alone.⁴⁶ At the time of diagnosis of lung cancer, it is estimated that up to 18% of patients have never smoked, 58% are former smokers, and 24% to 40% are current smokers.⁴⁷ About 20% of patients smoke at the time of cancer surgery, and half of these continue to smoke afterward.⁴⁷ There are extensive data documenting the adverse effects of smoking on both pulmonary function and clinical outcomes. Smoking decreases macrophage function, impairs vascular endothelial function, decreases coronary reserve, and places patients at increased risk for tachycardia, hypertension, and ischemia.^{48,49} In addition, smoking increases the risk for arterial desaturation and laryngospasm during anesthesia.⁵⁰ Smokers also have increased levels of carboxyhemoglobin (between 3% and 15%) that both compromise the total oxygen content of blood and impairs oxygen release at the tissue level by shifting the oxygen dissociation curve to the left.⁵¹ Recent multicenter outcome studies have confirmed the association between smoking and worse perioperative outcomes. Using data from the American College of Surgeons National Surgical Quality Improvement Program database, Turan and colleagues⁵² showed that smokers had an approximately 30% higher adjusted odds of postoperative mortality and major complications compared to nonsmokers. Another large database analysis using the Veterans Affairs Surgical Quality Improvement Program (with more than 390,000 patients) showed that past smokers have an approximately 20% higher odds of postoperative mortality or major complication.⁵³ In an STS database with almost 8000 patients undergoing lung resection surgery for cancer, Mason and associates⁵⁴ showed that smokers have a significantly increased risk for hospital mortality and pulmonary complications (hospital mortality 1.5% in smokers compared to 0.39% in nonsmokers), and that smoking cessation gradually mitigated these risks. However, they could not identify an optimal interval for smoking cessation.

There is some controversy over the timing of smoking cessation because some studies suggested an increase in PPCs in patients who quit smoking less than 8 weeks before surgery.^{55,56} The risk seemed to be higher in patients who quit closest to the day of surgery. However, more recent studies have not been able to show this increased risk in recent quitters. It does seem that the benefits increase with the duration of smoking cessation. A meta-analysis of 6 randomized trials and 15 observational studies of smoking cessation demonstrated a relative risk reduction of 41% in PPCs. In addition, each week of cessation increased the magnitude of the effect by 19%.⁵⁷ Another recent meta-analysis examined postoperative outcomes in patients who quit smoking less than 8 weeks before surgery compared to those who continued to smoke. They reported that there was no evidence of any positive or negative effect of late smoking cessation on PPCs.⁵⁸ Given these data, it seems prudent to encourage smoking cessation irrespective of surgical timing. The U.S. Public Health Service recommends that physicians strongly advise smokers to quit smoking because physicians' advice to quit has been associated with increased abstinence rates. Effective interventions include medical advice and pharmacotherapy such as nicotine replacement (which is generally safe in the perioperative period) and non-nicotine options such as bupropion and varenicline. Varenicline seems to be the most effective pharmacologic intervention to promote abstinence from smoking.^{59,60} It is important to note that the Food and Drug Administration has issued boxed warnings for both drugs because of reports of increased psychiatric symptoms or suicidal ideation.⁶¹

ASTHMA

Well-controlled asthma is unlikely to be a risk factor for either intraoperative or postoperative complications (for clinical aspects of asthma, see Chapter 42). However, poorly controlled asthma, evidenced by active wheezing, can increase PPCs.⁶² The combination of inhaled β -agonists such as albuterol and inhaled steroids with long-acting β -agonists is often very useful to achieve control of symptoms before surgery. If bronchospasm persists, a short course of low-dose systemic steroids may be considered and does not seem to have an impact on postoperative wound healing.⁶³ It is important to keep in mind that symptoms suggestive of asthma could in fact be due to other pathologic conditions such as pulmonary carcinoid,⁶⁴ tracheal stenosis,⁶⁵ and other endobronchial tumors,⁶⁶ and difficult-to-treat asthma should prompt a workup for these rarer conditions.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

COPD is increasingly being recognized as a disorder with both pulmonary and extrapulmonary manifestations, including an increased incidence of lung cancer⁶⁷ (for clinical aspects of COPD, see Chapter 44). Between 50% and 80% of patients with lung cancer have COPD, and the association is independent of the intensity of smoking.⁶⁸ Unlike well-controlled asthma, COPD is associated with an increased risk for PPCs.⁶⁹ As a general rule, the management of COPD before surgery is the same as for patients who

will not have surgery. The optimal management of COPD, including surgical approaches such as lung volume-reduction surgery, is discussed elsewhere in this textbook. (For clinical discussion of lung volume-reduction surgery, see Chapter 44.) Preoperative pulmonary rehabilitation may improve perioperative outcomes in these patients⁷⁰ (see later).

OBSESITY AND OBSTRUCTIVE SLEEP APNEA

More than 65% of Americans are overweight or obese. Obesity is associated with multiple comorbidities, including diabetes and heart disease. There is evidence that obesity is an independent risk factor for worse perioperative outcomes in many types of surgery⁷¹—however, in thoracic surgeries, the effect of obesity on outcome is less clear. As mentioned earlier, a high body mass index appeared to be protective in the STS database risk model study by Kozower and coworkers.¹⁶ A recent propensity-matched comparison of survival after lung resection in high versus low body mass index groups also suggested a protective effect of obesity in the setting of lung cancer.⁷² In another retrospective study, Dhakal and associates⁷³ did not find any adverse effect of obesity on postoperative morbidity or mortality following lung resection. It is unclear why obesity has no harmful or even a protective effect for perioperative outcomes—it is tempting to speculate that, in the setting of lung cancer, obesity is a marker of better nutritional and immune status, leading to better outcomes.

In contrast, patients with *obstructive sleep apnea* (OSA) have a higher incidence of (mainly respiratory) PPCs than those without OSA⁷⁴ (for discussion of OSA, see Chapter 88). In those undergoing hip or knee replacements, 39% of patients with OSA developed PPCs or cardiac complications compared to 18% of patients without OSA; 24% of the patients with OSA required intensive care unit admissions compared to 9% of patients without OSA.⁷⁵ Few investigations have identified the perioperative risks for OSA surgical patients,⁷⁶ but left heart failure or right heart dysfunction due to pulmonary hypertension could be responsible and should be sought. In particular, pulmonary hypertension is associated with significant perioperative risk.⁷⁷⁻⁷⁹ Because cardiovascular dysfunction in OSA patients can be modified by treatment,⁸⁰⁻⁸² it is important to identify patients with OSA and begin treatment. The use of standardized questionnaires such as the STOP (*Snoring, Tiredness during daytime, Observed apnea, high blood Pressure*) and STOP-Bang (*Body mass index, Age, Neck circumference, Gender*) forms have been validated in the perioperative setting and provide a simple and useful screening tool for OSA.⁸³ Current studies suggest that diagnosis and treatment of OSA can improve postoperative outcomes.^{83a}

LUNG RESECTION

The preoperative evaluation of patients for lung surgery differs from that for other surgeries. Not only are these patients more likely to have pulmonary disease, but the postoperative function may be impaired permanently because of the effects of the operation. In most other operations, the evaluation is primarily to optimize the anesthetic

Table 27-2 Resections That May Change Postoperative Pulmonary Function

Worse Function	Better Function
<ul style="list-style-type: none"> ■ Sublobar resection ■ Lobectomy ■ Pneumonectomy 	<ul style="list-style-type: none"> ■ Decortication/pleurodesis ■ Bleb resection ■ Volume reduction ■ Lung transplantation

and surgical plan and to prepare the patient, but in pulmonary resection, the evaluation determines whether or not the surgery can proceed.

PREDICTING POSTOPERATIVE FUNCTION

The challenge in assessing patients for pulmonary resection is predicting the postoperative course, both for the acute changes and postoperative morbidity, and for the final postoperative status. Depending on the type of operation, the eventual status may be better or worse than the current status (Table 27-2).

The typical method used to predict postoperative function is to use a regional ventilation-perfusion scan (V/Q scan using a radioactive gas) to estimate the proportion of lung function expected to be lost. This assessment was based on older studies that showed an excellent correlation.⁸⁴ More recent work, however, shows the nuances of postoperative functional prediction. For example, in one prospective study, the immediate postoperative function was significantly worse than the predicted postoperative FEV₁, and, although there was recovery in the first week, the FEV₁ did not reach the level predicted⁸⁵ (Fig. 27-4). In a study that followed patients over 3 months after discharge for lobectomy, pulmonary function was found to reach predicted levels at 1 month and in fact to surpass them at 3 months by approximately 10%⁸⁶ (Fig. 27-5).

In an STS report on their large registry of pulmonary resections (18,000 operations, 111 centers), pulmonary resection was associated with a 2% overall mortality.¹⁶ Significant predictors of morbidity and mortality included low preoperative FEV₁, renal failure, high American Society of Anesthesiologists class, steroid use, induction chemoradiation, and especially the type of resection, with pneumonectomy carrying more risk than lobectomy. Thoracoscopic surgery was somewhat protective.¹⁶

GUIDELINES FOR LUNG RESECTION

There are several consensus published guidelines for assessing a patient's suitability for pulmonary resection. Typically some measure of pulmonary function is used. Especially for more extensive resection (e.g., pneumonectomy), the possibility that the diseased lung may not be contributing a proportional share of function and thus may be safely resected is addressed by *predicted postoperative* (PPO) values. The estimate is usually calculated using ventilation-perfusion scans.

The American Thoracic Society/American College of Chest Physicians guidelines review cardiopulmonary exercise testing in detail but touch on preoperative evaluation only briefly. They recommend FEV₁ and DL_{CO} criteria as the

Figure 27-4 The actual FEV₁% measured in the first week after lobectomy compared to the predicted postoperative FEV₁%. In a prospective study of 125 patients undergoing lobectomy, the actual FEV₁% after surgery was lower than the predicted postoperative FEV₁% (PPO FEV₁%). Although the actual FEV₁% increased over 6 days, it remained below the level predicted (PPO FEV₁%). FEV₁% = FEV₁/FVC. (From Varela G, Brunelli A, Rocco G, et al: Predicted versus observed FEV₁ in the immediate postoperative period after pulmonary lobectomy. *Eur J Cardiothorac Surg* 30[4]:44–648, 2006.)

primary measures and, when these values are borderline, cardiopulmonary exercise testing has utility.⁸⁷ The British Thoracic Society recommends an initial FEV₁ evaluation and more detailed analysis in marginal cases.⁸⁸

PRINCIPLES OF CARDIOPULMONARY EXERCISE TESTING—STRENGTHS AND WEAKNESSES

(see Chapter 26)

Cardiopulmonary testing increases the demands of both the cardiovascular and respiratory system, but, given that the respiratory capacity is utilized only at peak exercise in healthy patients, exercise is usually limited by cardiac factors before respiratory function limits exercise capacity in normal individuals.⁸⁹ Exercise testing in patients is associated with severe complications in 1:10,000, and testing is contraindicated in patients with severe cardiac disease (e.g., cardiomyopathy, unstable angina, arrhythmias), uncontrolled asthma, significant infections, metabolic derangements, and uncooperative patients.⁹⁰

Not all investigations have found an association between exercise performance and a risk for perioperative complications.⁹⁰ Some of the issues with oxygen consumption measurements are that they are affected by muscle mass, body size, and level of fitness.⁸⁹ Therefore using *maximum oxygen consumption* ($\dot{V}O_2\text{max}$) may bias the preoperative assessment against older and obese individuals.⁸⁹

Some other issues that need to be considered are that $\dot{V}O_2/\text{kg}$ predictions based on preoperative measurements have significantly *overestimated* the degree of exercise capacity loss after an operation.⁹¹ Although the PPO $\dot{V}O_2/\text{kg}$ did not accurately predict postoperative exercise capacity, it was

nonetheless the best predictor for postoperative morbidity and mortality.⁹¹

It is also unclear whether preoperative exercise performance has any influence on long-term clinical outcomes. In one report, 68 of 86 patients categorized as high risk, with preoperative measured $\dot{V}O_2/\text{kg}$ less than 15 as well as having PPO FEV₁ of less than 33%, underwent lung resections. Although they had higher morbidities, the high-risk group had a low mortality of only 4% (3/68).⁹² Furthermore, the 68 high-risk patients who underwent resection had better 5-year outcomes than similar high-risk patients who were denied surgery.⁹² Patient outcomes after surgery are influenced by improvements in surgical techniques and postoperative care, as well as nonsurgical therapies for early-stage lung cancer, so that guidelines and other recommendations need to be revisited on a regular basis.⁸⁹

PREOPERATIVE PREDICTORS

Although a variety of testing schemes have been used for predicting postoperative complications after lung resection, $\dot{V}O_2\text{max}$ is currently considered the best predictor. In a 2007 meta-analysis of $\dot{V}O_2\text{max}$ as a predictor that pooled 14 studies and nearly 1000 patients, a higher $\dot{V}O_2\text{max}$ (20 versus 16 mL/kg/min) was found in the group without PPCs. DL_{CO} and FEV₁ were also somewhat higher in the group without complications; however, they were found to be less useful clinically than the $\dot{V}O_2\text{max}$.⁹³ $\dot{V}O_2\text{max}$ was also evaluated in a Cancer and Leukaemia Group B study that included 400 patients and a two-tier resectability evaluation. The first group based on FEV₁ and FEV₁-PPO criteria were considered “low risk.” Patients failing FEV₁ criteria were further stratified by a value of $\dot{V}O_2\text{max}$ greater than 15 mL/kg/min into “high risk” and “only at physician discretion.” The mortality and morbidity rate was higher for the high-risk group compared to the low-risk group, but overall survival was much better in all operative patients. There was also a tendency for the higher-risk patients to get a less extensive resection.⁹²

RECENT GUIDELINES FOR PREOPERATIVE TESTING IN LUNG CANCER PATIENTS

A recent evidence-based clinical practice guideline supported by the American College of Chest Physicians was published in the third edition of their supplement concerning the diagnosis and management of lung cancer.⁹⁴ Twelve recommendations were made and given grades for the level of existing evidence.⁹⁴ These recommendations for patients with lung cancer being considered for surgery are listed with our comments:

1. The preoperative assessment should be conducted by a multidisciplinary team. [This is reasonable, given that the patient will be cared for by a pulmonologist before and after surgery but will be cared for intraoperatively and perioperatively by an anesthesiologist and a surgeon.]
2. Evaluations should be done for patients regardless of age. [Many perioperative outcome studies have documented that the physiologic age is more important than the duration of life.]

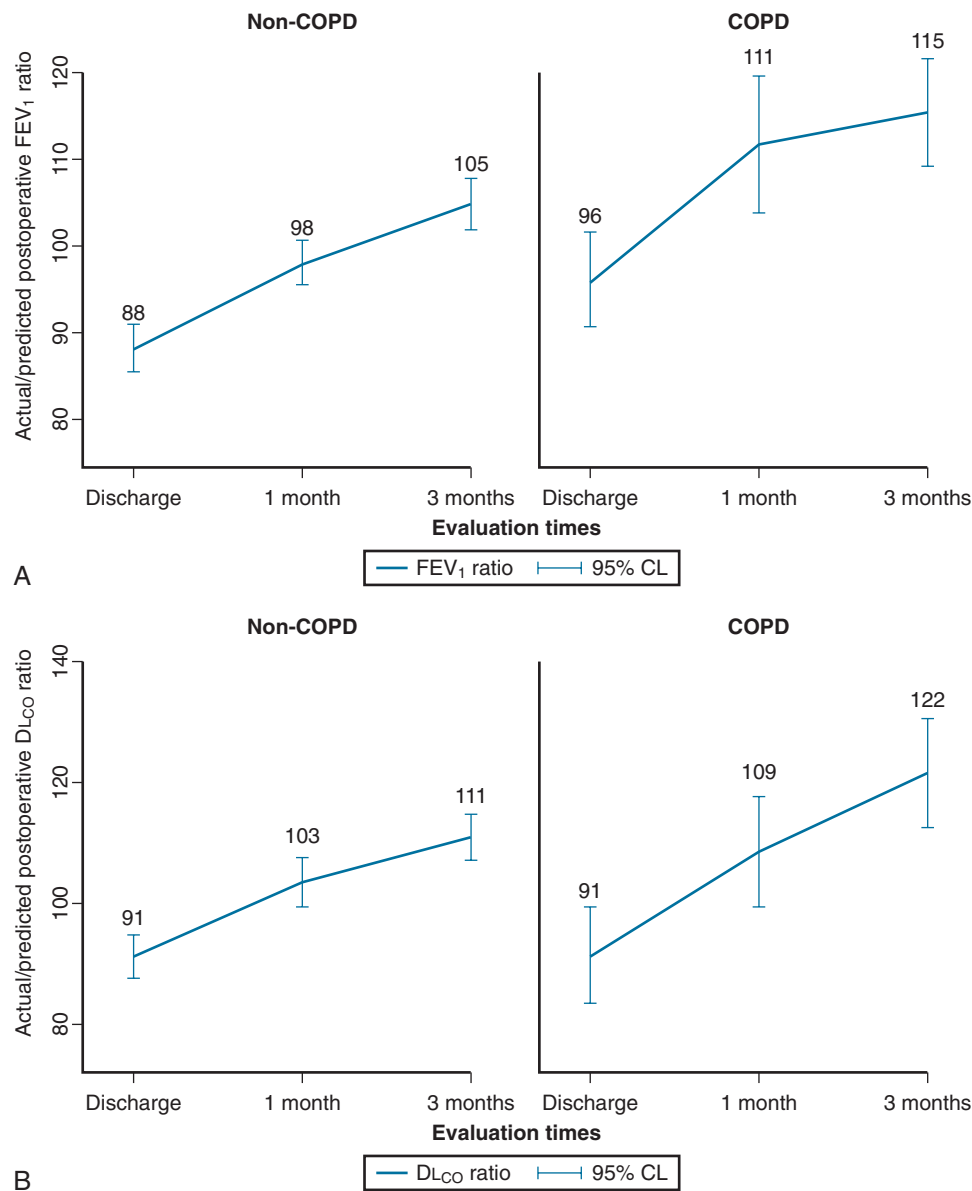

Figure 27-5 The ratios of actual to predicted postoperative values in patients with chronic obstructive pulmonary disease (COPD) or without COPD after lobectomy shown for FEV₁ (A) and DL_{CO} (B). COPD was defined as FEV₁ at or less than 80% and FEV₁/FVC less than 0.7. The predicted values were fairly accurate at 1 month in predicting the actual FEV₁ or DL_{CO} but underestimated the actual values at 3 months, especially in patients with COPD. CL, confidence limit. (From Brunelli A, Refai M, Salati M, et al: Predicted versus observed FEV₁ and DL_{CO} after major lung resection: a prospective evaluation at different postoperative periods. *Ann Thorac Surg* 83(3):1134–1139, 2007.)

- Cardiovascular risk should be managed according to existing guidelines for noncardiac surgery. [See earlier discussion of indications for coronary revascularization.]
- FEV₁ and DL_{CO} should be measured, and both PPO FEV₁ and PPO DL_{CO} should be calculated. If both of these PPO measurements are greater than 60% predicted, no further tests are recommended.
- However, if they are less than 60% predicted but above 30% predicted, a low-technology exercise test should be performed.
- If either of the PPO FEV₁ or the PPO DL_{CO} are less than 30% predicted, a formal cardiopulmonary exercise test should be done with measurement of the $\dot{V}O_2\text{max}$.
- Similarly, if a patient is considered for surgery who walks less than 25 shuttles [<400 m] on the shuttle walk test or climbs less than 22 m on a stair-climbing test, a formal cardiopulmonary exercise test with measurement of $\dot{V}O_2\text{max}$ is also recommended.
- If patients with lung cancer being considered for surgery have a $\dot{V}O_2\text{max}$ less than 10 mL/kg/min or less than 35% predicted, they should be counseled about minimally invasive surgery, sublobar resections, or nonsurgical treatment options. [See earlier comments regarding patients who were deemed high risk due to their exercise test results but had low perioperative mortality.⁹²]
- In patients with lung cancer who are being considered for surgery who undergo neoadjuvant therapy, it is

suggested that repeat pulmonary function testing with diffusing capacity be performed after completion of the neoadjuvant therapy. [These patients may be more prone to problems with drugs such as amiodarone—see earlier discussion.]

10. In patients with lung cancer in an area of upper lobe emphysema who are candidates for lung volume-reduction surgery, combined lung volume-reduction surgery and lung cancer resection is suggested.
11. In all patients with lung cancer being considered for surgery who are actively smoking, tobacco dependence treatment is recommended.
12. In patients with lung cancer being considered for surgery and deemed at high risk [PPO FEV₁ or the PPO DL_{CO} less than 60% predicted and $\dot{V}O_2$ max less than 10 mL/kg/min or less than 35% predicted], preoperative or postoperative pulmonary rehabilitation is recommended.⁹⁴

RISK MODIFICATIONS

Smoking Cessation

The most obvious risk modification available to patients is smoking cessation (see “Patients Who Smoke,” earlier). Interestingly, there had been a concern that there would be increased secretions and reactivity in the immediate withdrawal period. In the most relevant study of the timing of cessation before thoracotomy, Barrera and coworkers⁹⁵ found no difference in mortality or morbidity based on the duration of cessation and thus found no evidence of a paradoxical increase in complications among recent quitters. Smoking cessation is always to be encouraged before thoracotomy.

Surgical Approach

The surgical approach has implications for postoperative outcome. Based on the STS database of over 1000 patients undergoing lobectomy, a thoracoscopic approach had improved outcomes, including less AE, need for transfusion, and prolonged air leaks and shorter length of stay.⁹⁶ Similar findings have recently been found in a propensity score-matched study in which video-assisted thoracoscopic lobectomy was associated with a lower incidence of pulmonary complications (1.1% versus 12.1%), a shorter length of stay, and shorter operation time than lobectomy via thoracotomy.⁹⁷ Studies are now also showing that video-assisted thoracoscopic lobectomy offers similar long-term outcomes: in a study of patients with clinical stage I non-small cell lung cancer, video-assisted thoracoscopic lobectomy offered similar overall survival and disease-free survival as lobectomy by thoracotomy.⁹⁸

Exercise Training (For Clinical Exercise Testing, see Chapter 26)

It is interesting that $\dot{V}O_2$ max is a modifiable measurement. Preoperative interventions can improve exercise capacity in lung resection candidates. For COPD patients about to undergo lobectomy, Stefanelli and colleagues⁹⁹ found that “high-intensity training” improved $\dot{V}O_2$ max by 20%, an improvement that persisted for at least 2 months postoperatively. Static measures of lung function (DL_{CO} and FEV₁)

were unchanged by the training and decreased after surgery, as expected. In another study of 27 COPD patients facing lung resection, pulmonary rehabilitation improved $\dot{V}O_2$ max (from 13 to 19 mL/kg/min), arterial PO₂, and even FEV₁ to resectable levels, and subsequent resection was tolerated with only a 15% short-term morbidity.¹⁰⁰

Even if rehabilitation was not initiated before resection, there is evidence that postoperative exercise function can be improved with pulmonary rehabilitation after lung resection.¹⁰¹ Of course, merely improving the $\dot{V}O_2$ max does not guarantee better outcomes. The hope is that better function will allow a safer perioperative course in marginal patients¹⁰² and will improve overall postoperative function. However, the current literature is not yet sufficient to reach this conclusion. Certainly there is no hint of harm from pulmonary rehabilitation in this population, and the therapy matches recommendations for those in the general population with impaired pulmonary function.

Intraoperative Management

There is increasing recognition that intraoperative management can affect postoperative outcomes. Lung-protective ventilation, specifically smaller tidal volumes, use of positive end-expiratory pressure, and periodic recruitment maneuvers have significantly reduced postoperative pulmonary complications, need for reintubation, and length of stay in elective abdominal surgery.¹⁰³ The extension of these protective maneuvers to thoracic surgery is not simple. Pulmonary surgery usually benefits from one-lung ventilation, with the lung on the operative side deflated. However, because the pulmonary circulation is not routinely occluded, there is an obligatory pulmonary shunt and a real chance of hypoxemia during surgery. Traditionally, large tidal volumes, no positive end-expiratory pressure, and high fractional concentration of oxygen in inspired gas were used to combat hypoxemia.¹⁰⁴ However, there is now evidence that such management can cause postoperative pulmonary complications.¹⁰⁵ In a study designed to test different ventilatory strategies during one-lung ventilation for lung resection surgery, a protective lung ventilatory strategy was associated with significantly less postoperative lung dysfunction¹⁰⁵ (Fig. 27-6).

The choice of anesthetic agent also appears to influence the development of lung injury. For instance, in patients undergoing one-lung ventilation for thoracic surgery, the inhaled agents sevoflurane and desflurane suppressed the increase in a number of inflammatory markers (tumor necrosis factor, interleukin-1 β , interleukin-8) in bronchoalveolar lavage fluid as compared to intravenous propofol.¹⁰⁶

What factors predict hypoxia while performing one-lung ventilation? Patient position has a strong effect, with gravity improving flow to the dependent, ventilated lung.^{107,108} More disease in the non-ventilated lung, for instance as measured by end-tidal to arterial CO₂ gradient, predicts better tolerance of one-lung ventilation.¹⁰⁸ Overall, most thoracic anesthesiologists understand and work to minimize injury to the lungs during one-lung ventilation but also to preserve gas exchange.

Pain Management

A thoracotomy incision is considered to be one of the most painful surgical incisions and can significantly impair

Figure 27-6 Pulmonary complications seen after two ventilatory strategies in one-lung ventilation for lung resection. Fifty patients were ventilated with conventional ventilation (CV, blue) and 50 with protected lung ventilation (PV, brown). The pulmonary complications within 72 hours of the operation include arterial PO_2 /fractional concentration of oxygen in inspired gas (P/F) less than 300 mm Hg, new lung infiltrates, or acute lung injury (ALI). Note that fewer of the postoperative patients developed complications after protective ventilation for all complications except ALI. * $P < 0.05$ by Fisher exact test; † $P < 0.05$ by χ^2 test. (From Yang M, Ahn HJ, Kim K, et al: Does a protective ventilation strategy reduce the risk of pulmonary complications after lung cancer surgery?: a randomized controlled trial. *Chest* 139[3]:530–537, 2011.)

postoperative respiratory function¹⁰⁹ (for discussion of chest pain, see Chapter 31). In addition, inadequate relief of postoperative pain has been linked to a higher incidence of chronic postthoracotomy pain,¹¹⁰ poorer functional status,¹¹¹ and an adverse effect on quality of life.¹¹² Effective postoperative pain management is therefore a critical component of the perioperative management of thoracic surgery patients. The most common modality of pain management for patients undergoing thoracotomies (as opposed to thoroscopic procedures) has been *thoracic epidural analgesia* (TEA), which is commonly considered the gold standard for pain management in this patient population.¹¹³ In TEA, continuous infusion of a combination of local anesthetic and opioid into the epidural space selectively blocks pain fibers and sympathetic nerve fibers from the surgical site; the sympathectomy may reduce stress responses postoperatively. In a meta-analysis of 100 randomized trials comparing continuous epidural analgesia to parenteral opioids in thoracic, abdominal, and lower extremity surgery, Block and associates found that epidural analgesia provided significantly superior pain relief in all categories of surgery compared to parenteral opioids from the day of surgery through postoperative day 3¹¹⁴ (Fig. 27-7).

However, epidural analgesia is associated with a small but significant risk for major complications, including epidural hematoma formation, nerve damage (both via direct trauma and via drug toxicity), infection, and respiratory depression when opioids are used along with local anesthetics. Less serious but more frequent complications include hypotension, pruritus, nausea, and urinary retention. An emerging alternative to TEA in recent years has been the ultrasound-guided continuous thoracic *paravertebral block* (PVB). The PVB may be easier to place than a thoracic epidural, is unilateral (therefore less likely to cause complete sympathetic block and hypotension), and is less likely to cause significant bleeding or nerve damage.¹¹⁵ A number of studies have compared the two techniques in thoracotomy

Figure 27-7 Main pain scores for the epidural and PCA groups. Values represent means with 95% confidence intervals. Epidural anesthesia is more effective than PCA from 12 h on. (From Ali M, Winter DC, Hanly AM, et al: Prospective, randomized, controlled trial of thoracic epidural or patient-controlled opiate analgesia on perioperative quality of life. *Br J Anaesth* 104:292–297, 2010, Fig. 2.)

patients and have found analgesic efficacy to be equivalent in both TEA and PVB modalities, with an improved short-term side effect profile with PVB.^{115–118} Continuous PVB analgesia is therefore increasingly being employed in thoracic surgery. In the absence of an adequately powered, prospective, randomized trial, however, it remains difficult to endorse one technique unequivocally over the other.

Key Points

- Postoperative pulmonary complications are very common after thoracic surgery and contribute to poor outcomes for patients and increased costs.
- Increased risk for pulmonary complications and mortality are associated with patients who have higher American Society of Anesthesiologists status classification, induction chemoradiation, lower DL_{CO} , lower FEV_1 , and the need for a large resection (i.e., pneumonectomy or bilobectomy).
- Atrial fibrillation is very common after thoracic operations, and effective prophylaxis should be the goal.
- Patients who are smoking preoperatively should be encouraged to quit and should be given help to abstain from smoking.
- Preoperative pulmonary rehabilitation may improve perioperative outcomes in patients with COPD and may enable patients with marginal maximum oxygen consumption to improve and thus qualify for resection. Changes in surgical techniques and chemotherapies may also improve perioperative outcomes for these patients.
- Continuous epidural analgesia via a thoracic epidural using opioids and local analgesia provides optimal pain relief for up to 3 days after a thoracotomy.

FUTURE DIRECTIONS

Developing an Improved Framework of Disability

Institute of Medicine Framework Disease-Specific Impairment

INTRODUCTION

Respiratory impairment refers to an alteration in lung structure and/or lung function that results in decreased or limited functional ability and is usually manifested by dyspnea on exertion. Many respiratory diseases may cause impairment, from airway disease such as asthma and *chronic obstructive pulmonary disease* (COPD) to interstitial lung diseases. A pulmonary physician may be asked to evaluate impairment and/or disability, either for his or her own patients or for others in the context of an independent medical examination through a benefits or compensation program and/or to provide a statement about ability to work.

This chapter reviews the elements of an impairment evaluation. An overview of the major programs in the United States is presented. The program details, including how disability and/or impairment is determined under specific programs, is contained in the online version of the chapter. Impairment ratings are described using the framework for the assessment of respiratory impairment set forth by the *American Thoracic Society* (ATS)^{1,2} along with an overview of the most commonly used impairment rating methodology contained in the *American Medical Association* (AMA) *Guides to the Evaluation of Permanent Impairment*, hereafter referred to as the *AMA Guides*. However, the *AMA Guides* are not used by every benefit and compensation system. The evaluating physician must understand and follow the rules and specific requirements of the program under which the patient is being evaluated. The final determination on the award is usually made by personnel in the program or a judge, but the thoroughness of the medical report and its consistency with the program requirements will increase the weight given to the physician's medical

opinion. Finally, an overview of workplace protections for workers with lung disease is covered.

DEFINITIONS

There is a critical distinction between the terms *impairment* and *disability*. The terms *impairment* and *disability* are often used interchangeably, perhaps made more confusing by the fact that different benefits and compensation programs may use both terms but focus on one more than the other. *Impairment* occurs at the organ or organ system level. *Whole-person impairment* refers to the loss relative to the functioning of the body as a whole. *Disability*, in contrast, refers to the person in terms of limitation in the ability to perform normal activities, including personal, social, and work activities.

Physicians should understand that such determinations are medicolegal decisions, and they can have additional ramifications for the patient beyond that of providing a diagnosis. The physician may be asked to address causation (i.e., the physician may need to opine whether the respiratory condition was caused or at least aggravated by a certain factor, most commonly work, on a more-likely-than-not basis).

Although the terms "impairment" and "disability" are related, it is important that each term be applied in accordance with its precise definition. The definitions used in most existing benefits and compensation programs in the United States are based on the *World Health Organization's* (WHO's) *International Classification of Impairment, Disability, and Handicap* (ICIDH) model from 1980.³ This model was replaced by the *International Classification of Functioning, Disability, and Health* (ICF)⁴ in 2001, which uses different

definitions of these words. To avoid confusion, the definitions from the ICIDH are presented here. The ICF model and the framework for disability put forth by the *Institute of Medicine* (IOM) are presented in the “Future Directions” section.

IMPAIRMENT

Impairment refers to the degree of loss of normal use or function of a body part or organ. It was defined by the WHO as “any loss or abnormality of psychological, physiologic, or anatomic structure or function.”³ It was defined by the AMA as “a loss, loss of use, or derangement of any body part, organ system or organ function.”⁵

The essential elements that make up an impairment evaluation will vary to some degree according to the program or system through which the evaluation is being performed. Standard components typically include history, with occupational and environmental history and description of limitations in *activities of daily living* (ADLs); physical examination; and review of medical records and diagnostic test results that establish the respiratory condition.

Although *pulmonary function test* (PFT) results are the primary factor that determine the presence and degree of pulmonary impairment, some systems will specify that particular tests should be used for assessment of impairment or disability, whereas others allow physician discretion in choosing another test if he or she believes it to be a more accurate reflection of the patient’s true respiratory impairment. Some programs will only allow physicians with certain qualifications to perform impairment ratings. Additional elements that may need to be addressed can include delineation of permanent work restrictions, outline of future medical treatment requirements, and/or consideration of apportionment.

Before a physician can determine that a condition has resulted in permanent impairment or disability, the diagnosis should be well defined, the condition stable, and medical treatment either optimized or reasonable options exhausted. When these criteria are met, this is termed *maximum medical improvement* (MMI).

DISABILITY

Disability refers to any resulting alteration in the individual’s capacity to perform customary activities. It was defined by the WHO as “any restriction or lack of ability to perform any activity within the range considered normal for a human being.”³ The AMA defined *disability* as an “alteration of an individual’s capacity to meet or perform personal, social, or occupational demands or statutory or regulatory requirements because of an impairment.”⁵

Although the degree of impairment frequently correlates with the degree of disability, this is not always the case. The classic example of this is the loss of the fifth finger of the nondominant hand. Under the typical impairment rating system, the loss of this finger would be associated with a small impairment of the whole person. For the average person, this small impairment would result in a correspondingly small disability. For a concert pianist, this small impairment would be associated with significant disability, particularly in the context of work activities.

ADDITIONAL TERMS

Temporary impairment refers to impairment that exists only for a limited period of time after an injury or illness.

Temporary disability insurance covers partial compensation for loss of wages due to a non-work-related injury or illness. Partial compensation for lost wages, as well as medical benefits, are covered by workers’ compensation for work-related injuries and illness.

Permanent impairment can be assessed only once the patient has reached MMI. MMI is defined in the *AMA Guides*, Sixth Edition,⁶ as the “point in time in the recovery process ... when further formal medical or surgical intervention cannot be expected to improve the underlying impairment” and “symptoms can be expected to remain stable with the passage of time, or can be managed with palliative measures that do not alter the underlying impairment substantially.” This is termed “permanent and stationary” in some systems.

Whole-person impairment refers to the alteration in the functioning of the body as a whole and therefore can range from 0% (no impairment) to 100% (essential cessation of all body functions).

Permanent partial impairment is the numeric percentage of the loss of body functioning due to the loss or limitation in the functioning of the organ or organ systems affected. For most respiratory conditions, the primary organ involved is the lung, but at times, the pulmonary arteries or nose and throat may be affected.

Permanent total disability is the medicolegal determination that a person’s impairment precludes future gainful employment.

Handicap refers to the societal disadvantage caused by an impairment or disability. It was defined by the WHO in the ICIDH model as “a disadvantage for a given individual that limits or prevents fulfillment of that person’s normal role depending on sex, age, social and cultural factors.”³

CLINICAL APPROACH TO IMPAIRMENT EVALUATIONS

Although the term *impairment rating* is sometimes used interchangeably with the term *impairment evaluation*, the impairment rating itself is but a small part of what should be a comprehensive medical evaluation⁷ (Table 28-1). The physician must first fully understand the purpose and requirements of the program for which the evaluation is being conducted. The initial goal of the impairment evaluation should be to confirm the medical diagnosis,² through a thorough, detailed patient history, physical examination, and review of diagnostic testing results that established the diagnosis. The diagnosis or diagnoses should be clearly stated, along with extrapulmonary conditions that may be contributory to symptoms, limitations in ADLs, and/or impairment. A statement of MMI is often required. Factors important to the impairment rating itself include items from history, physical examination, and diagnostic testing results that reflect disease severity, including impact on normal ADLs,⁵ and current treatment requirements. The physician may be asked to make a statement on causation

Table 28-1 Components of a Respiratory Impairment Evaluation

1. Clear understanding of the rules and specific requirements of the program under which the individual is being evaluated.
2. Complete medical history
 - a. Complete occupational and environmental exposure history
 - b. Limitations in activities of daily living (ADLs)
3. Physical examination
4. Diagnostic testing
 - a. Tests that establish the diagnosis
 - b. Tests that identify extrapulmonary conditions contributing to impairment
 - c. Results used in the assessment of impairment
 - i. Pulmonary function tests
 - A. Spirometry
 - B. Single-breath diffusing capacity (DL_{CO})
 - ii. Cardiopulmonary exercise test (when indicated)
 - iii. Arterial blood gas measurement (when indicated)
5. Diagnosis
 - a. Assessment of causation, usually relationship to work (when indicated)
6. Impairment assessment
 - a. Statement of maximum medical improvement (MMI)
 - b. Impairment rating
 - c. Ability to work/work restrictions (when indicated)
 - d. Apportionment (if requested)
 - e. Future medical treatment

or apportionment. An outline of reasonably anticipated future medical course and treatment requirements should be given. The following sections describe the various aspects of an impairment evaluation, including the history to be taken, the examination to be conducted, and the testing to be obtained depending on the diagnosis considered and the type of evaluation being performed.

HISTORY

The *history of present illness* (HPI) is the standard, detailed respiratory history used by most pulmonologists, including symptoms of cough, cough with phlegm, wheeze, chest tightness, and shortness of breath. If present, details should be provided that include when the symptom started, exacerbating and alleviating factors along with temporal relationship, progression over time, and current status including frequency, severity, and response to any medication that is used. A scale for the rating of dyspnea is suggested in the *AMA Guides*, based on the Epidemiology Standardization Project,⁸ which also provides standardized questions for the assessment of other symptoms. Questions about conditions such as chronic rhinitis, postnasal drip, gastroesophageal reflux disease, cardiac disease, and other lung diseases, including smoking-related lung disease, may help the physician understand other possible contributors to respiratory symptoms. Although dyspnea is the primary limiting symptom of respiratory impairment, dyspnea can also result from nonpulmonary causes including cardiovascular disease, obesity, and deconditioning. Frequency, severity, treatment requirements, and duration of periodic exacerbations of diseases such as asthma and bronchiectasis should be well documented. Medications used or tried in the past for the treatment of the respiratory conditions should be described, along with a description of the relief afforded.

Constitutional symptoms are relevant in the HPI in patients with certain diseases, such as fever, sweats, chills, and fatigue in patients with hypersensitivity pneumonitis; chest pain, weight loss, and malaise in patients with asbestos-related lung disease; and night sweats and fatigue in patients with chronic beryllium disease.

A standard detailed past medical and surgical history, list of medications and allergies, family history, and review of systems will provide a good understanding of the patient as a whole. It will also allow the physician to identify other possible diseases that may be contributory to the patient's current status, as well as to assess potential treatment-related side effects. The standard social history should include smoking history, including amount, duration, and current smoking status.

An element that may be new to most pulmonologists is the need to obtain a detailed occupational and environmental history. This is necessary to help the physician address whether there is a relationship between a respiratory condition and past or ongoing workplace exposures. The occupational history is most easily performed in chronological order starting from childhood. Details about the period of time spent at each job, the job title, description of the work performed, and details about jobs or processes that may have produced dust, fumes, gas, or smoke should be described, including estimation of intensity, frequency, and duration of exposure. Questions about ventilation and use of respiratory protection can provide helpful clues, as well as whether or not there were any immediate symptoms noted. Chemical exposures, particularly any heavy exposures or exposures that resulted in symptoms, should be detailed. If available, the *Safety Data Sheet* (SDS), formerly called *Material Safety Data Sheet* (MSDS), may be reviewed because it can provide helpful information on the components of the chemicals used in the workplace and potential associated health effects. Unfortunately, MSDSs are not required to provide complete information, and thus some are more reliable than others.

An environmental history includes questions about heating, cooling, and humidification sources; pets including birds; hot tubs; water-damaged areas; and exposures from hobbies should also be obtained to determine whether there is a relationship between the disease and any environmental exposures.

In addition to the just-discussed components, the history should also include a description of how the condition affects the person's ability to perform normal ADLs. Questions most relevant to patients with pulmonary disease include ability to perform basic self-care such as showering; ability to walk, including estimated distance at own pace and at a fast pace or up a hill, estimated pace compared with others one's own age, and number of flights of stairs that can be climbed; and ability to perform indoor and outdoor home maintenance chores, as well as customary hobby, exercise, and job-related activities. There are a number of standardized methods by which to assess ability to perform ADLs, some of which are disease specific. A list of ADLs suitable for all conditions is outlined in the *AMA Guides*.^{5,9} Symptoms and limitations in ADLs that are consistent with the lung disease and objective testing data provide useful supporting information for the impairment rating. Dyspnea scales are often used and can be a helpful way to summarize

the relative degree of symptomatology or activity limitation.⁸ However, the degree to which dyspnea correlates with objective measures of pulmonary function and exercise performance is variable.¹⁰⁻¹³

PHYSICAL EXAMINATION

A complete physical examination should be performed, with focus on the respiratory and cardiovascular systems.^{2,7} A detailed description of the chest should be made, including any deformities or scars, abnormal motion, respiratory rate and effort, breath sounds, and percussion, which can help support the diagnosis. Vital signs should be documented including blood pressure and heart rate, which may affect ability to perform pulmonary function and exercise tests, as well as height and weight, because obesity can cause PFT and exercise test abnormalities and contribute to pulmonary symptoms. Signs of hypoxemia, such as cyanosis and clubbing, should be documented. Signs of cor pulmonale, such as jugular venous distention, right ventricular heave, and liver engorgement, and peripheral edema provide evidence of severe respiratory impairment in patients with respiratory disease.²

DIAGNOSIS, CAUSATION, AND MAXIMUM MEDICAL IMPROVEMENT

Any available or provided medical records should be summarized, with focus on the results of the diagnostic testing that help establish the diagnosis and/or severity of the condition. Medicolegal cases may often involve the review and summarization of large volumes of records. Some independent medical examinations require that only the records provided through the program be reviewed.

The list of medical diagnoses should start with the diagnosis of the condition for which the patient is being evaluated, including disease severity. The diagnosis of asthma associated with workplace exposures may fall under one of three different diagnoses: occupational asthma (new-onset asthma caused by a workplace exposure), work-aggravated asthma (existing asthma aggravated by a workplace exposure), and *reactive airways dysfunction syndrome* (RADS), which can result from a single high-level irritant exposure. Other diagnoses that may be contributory to symptoms, limitations in ADLs, or testing abnormalities should be clearly delineated.

If relevant, the diagnosis should also include a statement on *causation*, the physician's opinion as to whether or not a given workplace exposure has caused or aggravated an illness. This is a medicolegal determination, also known as *attribution*, made on a medically probable basis, also known as a "more-likely-than-not" basis. That is, the physician should be able to opine with greater than 50% certainty that the exposure(s) in the workplace caused the respiratory condition or worsened an underlying condition on the basis of objective criteria, such as change in treatment requirements. This criterion is less rigorous than would be required for scientific proof of a hypothesis (i.e., 95% certainty). This is important because in cases of respiratory illness, there may be multifactorial causation, frequently a long latency between initial exposure and clinical onset of disease, nonspecific clinical manifestations, incom-

plete understanding of dose-response relationships from epidemiologic studies, and lack of individual exposure data. Although recognition of these limitations is necessary, causation can be attributed in most cases on a more-probable-than-not basis by simply applying reasonable judgment. This process is easier when the exposure is known, the dose-response relationship is well characterized, and competing diagnoses are unlikely. The physician should clearly describe the specific substances at the workplace; their known health effects according to the medical literature; the relative dose, in terms of estimated intensity, frequency, and/or duration of exposure; and finally, why it is medically probable that the exposure(s) caused or resulted in permanent aggravation of the diagnosed medical condition in this worker. When one or more of these conditions are not met, attribution should be based on the answers to the following questions.

- Is the diagnosis clearly established, and is it biologically plausible (or consistent with the available epidemiologic data) that the disease could have been caused or aggravated by the exposure in question?
- Have competing diagnoses been adequately considered?
- Is the exposure of sufficient intensity and duration to have caused or aggravated the disease?
- Has there been an adequately long latent period, or is there a temporal relationship between onset of exposure and clinical manifestation of disease?

Some systems, such as most state workers' compensation and a Department of Labor Program, the *Energy Employees Occupational Illness Compensation Program* (EEOICP), require the physician to make a statement that the patient has reached MMI before performing an impairment rating. If the examining physician believes the condition is not stable or believes that there may be additional treatment reasonably likely to improve the condition, it is medically prudent to state this. What will happen logistically following determination of the MMI will depend on the specific program requirements. The examining physician should be aware of the ramifications of making these medicolegal determinations. For example, in the state workers' compensation system, determination of MMI will allow the worker to be awarded permanent impairment but will also result in the cessation of temporary benefits such as compensation for lost wages, as the case is closed by the workers' compensation insurance company.

GUIDES TO RESPIRATORY IMPAIRMENT RATINGS

AMERICAN THORACIC SOCIETY GUIDELINES FOR EVALUATION OF IMPAIRMENT OR DISABILITY

A number of systems have been used to determine respiratory impairment. Most base impairment primarily on lung function. In their "Guidelines for the Evaluation of Impairment/Disability Secondary to Respiratory Disorders," the ATS recommends that impairment due to most lung diseases be rated on the basis of *pulmonary function test*

Table 28-2 American Thoracic Society Impairment Categories, with Corresponding Description of Ability to Perform Job Demands

Category	Criteria	Ability to Perform Job Demands
Normal	$FVC \geq 80\%$ of predicted <i>and</i> $FEV_1 \geq 80\%$ of predicted <i>and</i> $FEV_1/FVC \times 100 \geq 75\%$ <i>and</i> $DL_{CO} \geq 80\%$ of predicted	
Mildly impaired	FVC 60–79% of predicted <i>or</i> FEV_1 60–79% of predicted <i>or</i> $FEV_1/FVC \times 100$ 60–74% <i>or</i> DL_{CO} 60–79% of predicted	Usually not correlated with diminished ability to perform most jobs
Moderately impaired	FVC 51–59% of predicted <i>or</i> FEV_1 41–59% of predicted <i>or</i> $FEV_1/FVC \times 100$ 41–59% <i>or</i> DL_{CO} 41–59% of predicted	Progressively lower levels of lung function correlated with diminishing ability to meet the physical demands of many jobs
Severely impaired	$FVC \leq 50\%$ of predicted <i>or</i> $FEV_1 \leq 40\%$ of predicted <i>or</i> $FEV_1/FVC \times 100 \leq 40\%$ <i>or</i> $DL_{CO} \leq 40\%$ of predicted	Unable to meet the physical demands of most jobs, including travel to work

DL_{CO} , single-breath carbon monoxide diffusing capacity; FEV_1 , forced expiratory volume in 1 second; FVC , forced vital capacity.

From American Thoracic Society (ATS): Evaluation of impairment/disability secondary to respiratory disorders. American Thoracic Society. *Am Rev Respir Dis* 133:1205–1209, 1986.

(PFT) results.² Pulmonary function testing is described in Chapter 25. The results of the ATS impairment system, based on PFTs, place individuals into four impairment categories. Each of these categories provides a corresponding description of the associated ability to perform job demands (Table 28-2). The ATS did not include a system by which to assign an associated numerically derived percentage of whole-person impairment, on which monetary awards are typically based. Therefore the ATS guidelines did not lend themselves to use in most compensation systems.

AMERICAN MEDICAL ASSOCIATION GUIDES TO THE EVALUATION OF PERMANENT IMPAIRMENT

The *AMA Guides*, Fifth Edition, adapted the ATS Guidelines by adding a system through which to assign a numerically derived percentage of whole-person impairment within each of the four impairment classes.¹⁴ Although the *AMA Guides*, Fifth Edition, is no longer the most current edition, the methodology is presented here because it is directly based on ATS Guidelines and because many compensation systems have not yet adopted the Sixth Edition. The *AMA Guides*, Fifth Edition, assigned the following associated ranges of whole-person respiratory impairment to each of the four ATS classes: class 1 impairment is equal to 0% whole-person impairment, class 2 (mild) impairment ranges from 10% to 25% impairment, class 3 (moderate) ranges from 26% to 50% impairment, and class 4 (severe) ranges from 51% to 100% whole-person impairment. After determining the class of impairment based on *forced vital capacity* (FVC), *forced expiratory volume in the first second* (FEV_1), FEV_1/FVC , *single-breath diffusing capacity* (DL_{CO} , or $\dot{V}O_2$, the physician determines the final numeric percentage whole-person impairment on the basis of where the test results fall within that range of impairment, as well as other factors, including impact of the respiratory condition on the ability to perform ADLs.

The *AMA Guides*, Sixth Edition, adopts a different methodology, defining 4 classes of impairment: class 0: 0% whole-person impairment, class 1 (minimal) ranges from 2% to 10% impairment, class 2 (mild) ranges from 11% to 23% impairment, class 3 (moderate) ranges from 24%

to 40% impairment, and class 4 (severe) ranges from 45% to 65% whole-person impairment.¹⁵ The “key factor” is the objective test data, FVC, FEV_1 , FEV_1/FVC , and DL_{CO} , using the measurement most relevant to the disease process.¹⁵ $\dot{V}O_2$ may be considered as the key factor if one of the other pulmonary function test results is abnormal. The specific value within the impairment class is determined by the physical examination findings, dyspnea, and treatment requirements. The maximum whole-person impairment in the *AMA Guides*, Sixth Edition, for most respiratory disorders is 65% whole-person impairment, rather than 100% whole-person impairment in previous editions, although this rating may still be combined with impairment in other organ systems.

Because a person can never have more than 100% impairment of the body, impairment in any additional organ system needs to be combined rather than added to the respiratory impairment. Each edition of the *AMA Guides* contains a special combining table for this purpose.

CLASSIFICATION OF IMPAIRMENT RESULTING FROM SPECIFIC PULMONARY DISEASES

Regardless of the rating system used, the greatest weight should be placed on objective data.

Asthma (for details concerning diagnosis and management of asthma, see Chapter 42)

Rating asthma according to the standard respiratory disorder methodology can both underestimate and overestimate impairment, given the episodic and variable nature of airflow limitation and bronchial hyperresponsiveness.¹⁶ The ATS developed “Guidelines for the Evaluation of Impairment/Disability in Patients with Asthma” in 1993 to reflect the true impairment due to this condition.¹ First, a worker with objectively confirmed asthma must be determined to be at MMI or to have achieved optimal therapeutic goals (i.e., minimum medication that obtains the best overall outcome).¹⁵ To rate asthma impairment according to ATS methodology (Table 28-3), the postbronchodilator FEV_1 , reversibility (% change with bronchodilator), or methacholine challenge results (provocative concentration of methacholine inducing a 20% drop in FEV_1 [PC_{20} in mg/mL]), and minimum medications required to maintain

Table 28-3 American Thoracic Society Impairment Rating Guidelines for Asthma**A. Postbronchodilator FEV₁**

Score	FEV ₁ (% predicted)
0	> lower limit of normal
1	70– lower limit of normal
2	60–69
3	50–59
4	<50

B. Reversibility of FEV₁ or Degree of Airway Hyperresponsiveness*

Score	% FEV ₁ change	PC ₂₀ (mg/mL or equivalent)
0	<10	>8
1	10–19	8–>0.5
2	20–29	0.5–>0.125
3	≥30	≤0.125
4	—	—

C. Minimum Medication Need†

Score	Medication
0	No medication
1	Occasional bronchodilator, not daily, and/or occasional cromolyn,‡ not daily
2	Daily bronchodilator and/or daily cromolyn‡ and/or daily low-dose inhaled steroid (<800 µg beclomethasone or equivalent)
3	Bronchodilator on demand and daily high-dose inhaled steroid (>800 µg beclomethasone or equivalent) or occasional course (1–3/year) systemic steroid
4	Bronchodilator on demand and daily high-dose inhaled steroid (>1000 µg beclomethasone or equivalent) and daily systemic steroid

D. Summary of Impairment Rating Classes‡

Impairment Class	Total Score
0	0
I	1–3
II	4–6
III	7–9
IV	10–11
V	Asthma not controlled despite maximal treatment (i.e., FEV ₁ remaining < 50% despite use of ≥ 20 mg prednisone/day)

*When FEV₁ is above the lower limit of normal, the PC₂₀ value should be determined and used for rating of impairment; when FEV₁ is < 70% predicted, the degree of reversibility should be used; when FEV₁ is between 70% predicted and the lower limit of normal, either reversibility or the PC₂₀ can be used.

Reversibility with bronchodilator is calculated as

$$\frac{\text{FEV}_1 \text{ postbronchodilator} - \text{FEV}_1 \text{ prebronchodilator}}{\text{FEV}_1 \text{ prebronchodilator}} \times 100\%$$

Airway responsiveness is expressed as that concentration of bronchoconstrictor agents that will provoke a fall in FEV₁ of 20% from the lowest postsaline value. Plot the concentration of methacholine or histamine against the fall in FEV₁ using a logarithm scale for the doubling concentrations. The PC₂₀ is obtained by interpolation between the last two points. The formula for linear interpolation of the PC₂₀ from the log dose response curve is as follows:

$$\text{PC}_{20} = \text{antilog } C1 + \frac{(\log C2 - \log C1)(20 - R1)}{(R2 - R1)}$$

Where C1 = second last concentration (<20% FEV₁ fall)

C2 = last concentration (>20% FEV₁ fall)

R1 = % fall FEV₁ after C1

R2 = % fall FEV₁ after C2

†The need for minimum medication should be demonstrated by the treating physician, e.g., previous records of exacerbation when medications have been reduced.

‡Very limited current use.

§The impairment rating is calculated as the sum of the patient's scores from Tables A, B, and C.

From the American Thoracic Society, Medical Section of the American Lung Association: Guidelines for the evaluation of impairment/disability in patients with asthma. *Am Rev Respir Dis* 147:1056–1061, 1993.

this status are assigned scores using Tables 28-3A, B and C. The class of impairment is defined by the sum of the asthma scores based on Table 28-3D. The *AMA Guides*, Fifth Edition, adopted the ATS methodology and assigned a numeric range of whole-person impairment for each impairment class that is equivalent to the impairment assigned for general respiratory conditions.¹⁴ Additionally, ATS added a fifth class of impairment, defined as asthma not controlled despite maximal treatment (i.e., FEV₁ remaining <50% despite use of ≥20 mg of prednisone daily). The *AMA Guides*, Sixth Edition, additionally recommends that an impairment rating be performed after the patient has achieved optimal therapeutic goals, and that it is prudent to wait at least 2 years after diagnosis and removal from exposure in cases of occupational asthma.¹⁵ In the *AMA Guides*, Sixth Edition, PC₂₀ mg/mL is used as the primary “key factor” by which to determine the class of asthma impairment, although postbronchodilator FEV₁ may be used as an alternative. Minimum medication requirements and frequency of attacks are used to determine the specific numeric rating within the class.¹⁵

Bronchiectasis (for further discussion, see Chapter 48)

Rating conditions such as bronchiectasis by the standard pulmonary function testing methods also can underestimate impairment because it is the recurrent episodes of infection and inflammation that cause intermittent respiratory symptoms, respiratory dysfunction, and limitations in ADLs, often with normal lung function in between episodes. The *AMA Guides*, Fifth Edition, acknowledge that this method will be applicable only in “limited cases,” but they will allow the physician to assign a rating on the basis of the extent and severity of these episodes and their impact on ADLs, with objective supporting evidence documented.¹⁴ The *AMA Guides*, Sixth Edition, does not delineate a specific methodology for this condition.¹⁵

Sleep Disorders (for further discussion, see Chapters 85–89)

Sleep disorders are recognized in the *AMA Guides*, Sixth Edition, as a condition that may cause impairment not well estimated by standard pulmonary function testing or exercise testing.¹⁵ Both the *AMA Guides*, Fifth and Sixth Editions, describe the importance of obtaining sleep testing in an accredited laboratory, and grading severity based on the number of apnea and hypopnea episodes observed during polysomnography and the severity of hypoxia.^{14,15} However, as there are no standardized, well-documented criteria for determining level of impairment, the rating should be performed by a sleep specialist. The *AMA Guides*, Sixth Edition, specifies that the rating should not exceed 3% whole-person impairment.

Lung Cancer (for discussion of clinical aspects of lung cancer, see Chapter 53)

The *AMA Guides*, Fifth and Sixth Editions, recommend one of two methods be used for rating permanent impairment due to lung cancer.^{14,15} All individuals with lung cancer are considered severely impaired at the time of diagnosis. At 1 year after diagnosis, if there is still evidence of tumor or tumor recurrence, the person is considered to be severely impaired. If there is no residual tumor or recurrence, the

impairment rating is performed according to the standard rating methodology for respiratory diseases.

Diseases of the Pulmonary Arteries (for discussion of disorders of the pulmonary vascular bed, see Chapters 57–61)

Diseases rated by this methodology include pulmonary artery hypertension, cor pulmonale, and pulmonary emboli. In the *AMA Guides*, Fifth Edition,¹⁷ the rating is determined by the presence or absence of physical examination signs (right ventricular heave, increased *pulmonic component* [P₂] of the *second heart sound* [S₂], peripheral edema) and symptoms of right heart failure (dyspnea), as well as the observed *pulmonary artery pressure* (PAP). In the *AMA Guides*, Sixth Edition,⁹ the objective findings including PAP, B-type natriuretic peptide, and $\dot{V}O_2$ are the “key factors” that determine the class of impairment. The specific percentage assigned within the class is determined by history (dyspnea and activity limitations) and physical examination findings (signs of right heart failure).

Conditions of the Upper Airways

(for further discussion, see Chapter 49)

The *AMA Guides*, Fifth Edition,¹⁸ contain methodology by which to assign impairment due to obstruction of the upper airway, larynx, trachea, and/or bronchi, based on degree and location(s) of the obstruction, nature of the activities that trigger dyspnea, as well as need for ventilation. The *AMA Guides*, Sixth Edition, uses the nature of the activities that trigger dyspnea as the “key factor” in determining impairment class and physical examination findings and objective test results, such as sinus CT or findings on laryngoscopy determine the final numeric rating.¹⁹ There are also methods for the rating of voice/speech impairment, based on audibility, intelligibility, and functional efficiency in the *AMA Guides*, Fifth Edition. These factors are also used to define the “key factor” for impairment class in the *AMA Guides*, Sixth Edition, as well as consideration of stroboscopy, objective voice and speech measures, and Voice Handicap Index. It is important to note that there are differences in what defines impairment within a given class in the two editions.

ROLE OF DIAGNOSTIC TEST RESULTS IN IMPAIRMENT RATINGS

RADIOGRAPHIC DATA

Documentation of chest radiograph or *computed tomography* (CT) scan abnormalities consistent with the lung disorder is frequently required to establish evidence of disease, particularly for diseases such as pneumoconiosis. The chest imaging findings may correlate poorly with the physiologic findings, especially in patients with obstructive lung disease.

Some programs require that chest radiographs be read by a *National Institute of Occupational Safety and Health* (NIOSH)-certified B-reader and classified according to the *International Labour Organization's* (ILO's) classification system.²⁰ This radiographic interpretation system was devised in an attempt to report the presence, appearance, and extent of

radiographic changes consistent with pleural and parenchymal evidence of pneumoconiosis in an objective and consistent manner. Chest radiographic findings of opacities with an ILO profusion score of at least 1/0 are “consistent with” asbestosis and will be accepted for compensation purposes by programs such as the Department of Labor for that condition. If the opacities are small and irregular (classified as “s” and “t”) and are found predominantly in the middle and lower lobes or are found in conjunction with pleural plaques, these findings are highly consistent with a diagnosis of asbestosis.

Whereas the ILO interpretation may help raise suspicion of pneumoconiosis, or provide sufficient evidence of disease in the correct clinical situation, the physician needs to determine on a clinical basis whether additional testing is necessary to establish a medical diagnosis and determine whether treatment is necessary. The physician should note that additional testing may or may not be covered by the benefits or compensation program. Because of the variability in the extent of radiographic findings and the degree of physiologic impairment, none of the major programs or rating systems uses radiographic findings in the assessment of impairment due to lung disease. The NIOSH website provides a search tool by which to find certified B-readers by state and country.²¹

A standardized CT classification system similar to the ILO system called the *International Classification of High-Resolution Computed Tomography for Occupational and Environmental Disease* has been proposed.²² Although this CT classification system was found to have satisfactory inter-reader reliability by an international panel of experts,²³ the assessment mainly focused on one lung disease, asbestos-related lung disease, so the generalizability of this system is not clear. Neither this nor any other standardized system for reporting CT findings of pneumoconiosis is currently in widespread use.

PULMONARY FUNCTION TESTING

(for further discussion, see Chapter 25)

PFTs are the most important tests, both from a diagnostic standpoint and in their use to determine impairment for most respiratory conditions. Both the ATS² and the *AMA Guides* specify the use of FVC, FEV₁, FEV₁/FVC, and DL_{CO}. Some programs mandate that pulmonary function testing be performed pre- and post-bronchodilator and should be done in patients with low FEV₁ or diagnoses of reversible airflow limitation. The ATS specifies that individuals should be evaluated only after they have received an accurate diagnosis and while they are receiving optimal therapy.² This is consistent with the *AMA Guides'* requirement that the patient be at MMI, as described previously. Measurement of height in stocking feet is recommended, as is measurement of arm span (distance between the tips of the middle fingers with arms outstretched) in cases of spinal deformity.^{2,24}

Both ATS and the *AMA Guides* emphasize the importance of only using test results that meet the quality standards defined in the latest ATS statement “Standardization of lung function testing.”²⁵ This document governs the equipment, quality assurance, and techniques that should be used to perform lung function testing, in addition to the assessment of the quality of the test and the method of

interpretation. If a physician has concern that the PFTs were not performed in a manner consistent with the ATS Guidelines, including acceptability and reproducibility, then the physician should request repeating the test. An exception happens when the patient has consistently demonstrated less than optimal technique on past tests despite language-appropriate education and encouragement. This consistent, unacceptable test performance may be due to overall debilitation, pain, or language barrier and when it is unlikely that repeating the test will yield improved results. Test results that are markedly worse than those of prior tests raise concern that there has been an exacerbation of the underlying condition and that the patient is not at MMI, or it may be that the patient gave less than full effort; regardless, such results would not be considered to reflect the patient's permanent impairment status. Options include informing the subject of the discrepancy and repeating the test or using the results "as a subsidiary and not the main criterion."²⁶

When evaluating PFTs for impairment, the normal values of the laboratory performing the test should not be used, but rather the normal values of the impairment rating system. For example, the ATS and *AMA Guides*, Fifth Edition, reference population normal values derived from Crapo and coworkers,²⁷ while the *AMA Guides*, Sixth Edition, reference *National Health and Nutrition Examination Survey* (NHANES) III-derived prediction equations.²⁸

DL_{CO} , measured by the single-breath method of Ogilvie and colleagues²⁹ and interpreted according to Crapo and Morris,³⁰ is suggested by both ATS and the *AMA Guides*. Both recommend correction by the methodology of others for factors including hemoglobin, carboxyhemoglobin,^{2,14} and altitude and alveolar volume,² but correction methodology and interpretive strategies are not explicitly described in the rating criteria. The most recent ATS statement on DL_{CO} describes explicit criteria for evaluating acceptability and repeatability, as well as adjustment for hemoglobin, supplemental oxygen, altitude, and carboxyhemoglobin, while noting that further study is necessary before specific recommendations for lung volume adjustment can be made.³¹ In a separate statement, the ATS has noted that low DL_{CO} along with low DL_{CO} corrected for alveolar volume (DL_{CO}/VA) suggests parenchymal abnormalities as the cause of the impairment but recommends examining the two separately.²⁵ Neither the ATS nor the *AMA Guides* utilize DL_{CO}/VA in assessing impairment.

Maximal voluntary ventilation (MVV) and $FEV_{25\%-75\%}$ are not recommended for use by ATS or the *AMA Guides* in impairment evaluation. ATS defines a restrictive ventilatory defect as a reduction in total lung capacity (TLC) below the lower limit of normal (i.e., below the fifth percentile of the predicted value), with a normal FEV_1/FVC ratio.²⁵ TLC is not included in the standard rating criteria in either the ATS or the *AMA Guides*. Although the *AMA Guides*, Sixth Edition, caution that a true restrictive defect may not be present even with a reduced FVC in the setting of a normal or increased FEV_1/FVC , FVC continues to be the test used in the rating of impairment. Low FVC can be caused by submaximal inspiratory or expiratory effort and/or peripheral airflow obstruction.²⁵ One study showed the predictive value of reduced FVC to be less than 60% for the presence of true restrictive deficit.³² Others report concern about

reduced lung function test results, including FVC, in obesity,^{33,34} but there are no established criteria by which to account for obesity in testing.

CARDIOPULMONARY EXERCISE TESTING

(see Chapter 26 for details)

Neither the ATS nor the *AMA Guides* recommend the routine use of exercise test results in the determination of permanent impairment, but maximal exercise test results, specifically $\dot{V}O_2$, should be used in specific circumstances. ATS recommended that exercise test results be used in cases where the resting PFTs do not reflect the true impairment present.² For example, studies have demonstrated that alveolar-arterial oxygen pressure difference ($A-a$) PO_2 during exercise is a better reflection of impairment due to gas exchange abnormality than DL_{CO} .³⁵ Although exercise limitation does not necessarily correlate with resting lung function testing,^{36,37} exercise testing can be helpful in cases where there is a large discrepancy between symptoms and resting physiology,³⁵ providing a more precise measurement of work capacity.³⁸

Airflow limitation and gas exchange abnormality help define the relative degree to which respiratory disease is contributing to exercise limitation. When exercise limitation is present, nonrespiratory causes of exercise limitation should be considered as well, including cardiovascular disease, deconditioning, and neuromuscular disease.³⁹ The ATS guidelines for respiratory impairment note that exercise testing can be used as a valid measure of respiratory impairment when the following criteria are met: (1) if exercise testing is not terminated for other nonpulmonary reason, (2) if there is low breathing reserve at termination, and (3) if there is absence of erratic overventilation at submaximal levels with failure to achieve anaerobic threshold. However, there are no details provided on how these criteria should be met and the *AMA Guides* do not delineate a specific methodology. The reason for test termination should be noted because tests terminated early due to nonrespiratory causes such as excessive blood pressure, cardiac abnormality, or leg pain do not reflect maximum exercise tolerance.

To determine work capacity, and thus impairment, ATS requires use of $\dot{V}O_{2max}$ to place workers into one of three categories of work tolerance, assuming that workers can comfortably perform sustained work at 40% of $\dot{V}O_{2max}$ and that O_2 requirements of the workers' jobs are known (Table 28-4). Major limitations to this approach include the following: (1) little published data that substantiate its use; (2) heterogeneous methods of assessing maximal oxygen uptake⁴⁰; (3) the fact that actual work performed by workers with the same job title can vary markedly from employer to employer or among employees with differing seniority at the same employer; (4) the questionable relationship between exercise tolerance on the treadmill or bicycle and performance on the job⁴¹; and (5) the lack of consideration of modifying factors such as the need to talk or use *personal protective equipment* (PPE) while performing the work.⁴² The average energy requirements of a number of jobs are listed in Table 28-5. The *AMA Guides*, Fifth and Sixth Editions, both consider a $\dot{V}O_{2max}$ greater than 25 mL/kg/min to place one into the lowest (least) category of impairment (class 1 and class 0, respectively) and a $\dot{V}O_{2max}$ less than

Table 28-4 American Thoracic Society Interpretation of Exercise Test Results Using $\dot{V}O_{2\max}$

$\dot{V}O_{2\max}$	METS	Estimated Work Ability
≥ 25 mL/kg/min	≥ 7.1	Continuous heavy exertion throughout an 8-hour day in all but the most physically demanding jobs
15–25 mL/kg/min and Metabolic demands of the work $\leq \dot{V}O_{2\max}$		Able to perform that job comfortably, assuming there are no frequent or extended periods (5 min) requiring exertion substantially $>40\%$ $\dot{V}O_{2\max}$
≤ 15 mL/kg/min	≤ 4.3	Unable to perform most jobs because they would be uncomfortable traveling back and forth

METS, the energy demand in liters of oxygen consumption per minute/basal oxygen consumption (3.5 mL/kg/min); $\dot{V}O_{2\max}$, maximal oxygen consumption.

From American Thoracic Society (ATS): Evaluation of impairment/disability secondary to respiratory disorders. *Am Rev Respir Dis* 133:1205–1209, 1986.

Table 28-5 Energy Requirements Expressed as Oxygen Uptake ($\dot{V}O_2$) of Various Types of Work

Level of Work	$\dot{V}O_2$ (APPROXIMATE)		
	mL/kg/min	L/min	METS
Light to moderate work (sitting)			
Clerical	5.6	0.42	1.6
Using repair tools	6.3	0.47	1.8
Operating heavy equipment	8.8	0.66	2.5
Heavy truck driving	12.6	0.95	3.0
Moderate work (standing)			
Light work, own pace	8.8	0.66	2.5
Janitorial work	10.5	0.79	3.0
Assembly line (lifts > 45 lb)	12.3	0.92	3.5
Paper hanging	14.0	1.05	4.0
Standing and/or walking (arm work)			
General heavy labor	15.8	1.19	4.5
Using heavy tools	21.0	1.58	6.0
Lift and carry 60–80 lb	26.2	1.97	7.5

METS, the energy demand in liters of oxygen consumption per minute/basal oxygen consumption (3.5 mL/kg/min).

Adapted from Becklake M: Organic or functional impairment. *Am Rev Respir Dis* 129:S96–S100, 1984.

15 mL/kg/min to place one into the highest (greatest) category of impairment (class 4). The use of exercise testing and $\dot{V}O_{2\max}$ overestimates impairment in older workers. As an alternative, it has been proposed that $\dot{V}O_{2\max}$ be expressed as percent of predicted,⁴³ although this is not in standard use at this time. Although advances have been made, the recent ATS Statement on Cardiopulmonary Exercise Testing³⁹ noted that a comprehensive updated framework for impairment/disability is needed urgently.

BLOOD GAS ANALYSIS

Arterial blood gas analysis is not used for impairment rating purposes on a routine basis. Resting arterial PO_2 does not

correlate with exercise capacity. As a result, arterial hypoxemia at rest is, by itself, not evidence of severe impairment in exercise tolerance. ATS recommends it only be used in “selected patients” under “rigidly controlled laboratory conditions” and should be documented on at least two occasions separated by at least 4 weeks.² They consider hypoxemia to be evidence of severe impairment only when accompanied by evidence of cor pulmonale. Arterial blood gas analysis was also considered to be a test infrequently indicated in the evaluation of impairment in the *AMA Guides*, Fifth Edition.¹⁴ It is not included in the Sixth Edition.¹⁵

ADDRESSING DISCREPANCIES BETWEEN OBJECTIVE AND SUBJECTIVE DATA

A description of the severity of the disease or condition should be given. This can be difficult when there is a discrepancy between the severity reported by the patient and the severity of the disease based on the results of the diagnostic testing. It is important that the physician distinguish between data that are *objective* (findings evident to the examiner in a reproducible manner and not dependent on only the patient’s perceptions), including physical signs and diagnostic testing results, and *subjective* data, which are reported by the patient, such as symptoms perceived by the patient only and not evident to the examiner. Normally, the two will be similar, making the history, physical examination, and diagnostic testing findings all helpful in the assessment of true functional impairment. If the subjective complaints are not consistent with the objective findings, the physician should first be sure there is no coexisting disease process responsible for the symptoms. For example, dyspnea may also be caused by nonrespiratory disorders such as cardiac disease and anemia. *Organic impairment* refers to the presence of objective findings of respiratory dysfunction or disease. *Functional impairment* refers to dyspnea for which an objectively measured abnormality of organ function cannot be identified. Recognizing that tests for organic impairment are not perfectly sensitive, the contribution of functional impairment can range from “negligible” to “perhaps accounting for the entire extent of a patient’s dyspnea.” When there is a discrepancy between the subjective and the objective data, and other medical conditions have been excluded as possible contributors to the subjective complaints, several steps should be taken. The first and foremost is to review the purpose of the evaluation with the patient to ensure that a lack of comprehension of either questions or performance of PFTs does not exist. Second, an evaluation of test performance, including cooperation and the results of effort-independent tests such as functional residual capacity, may be of some use. Examination of test results for comparability over time may show evidence of consistency or the lack thereof. Finally, exercise testing may shed considerable light on a patient’s level of effort by demonstrating the relationships of heart rate and ventilatory rate at workloads actually achieved to the predicted maximal values.

Dyspnea due to functional impairment may result from subconscious effects on the perception of symptoms or from outright malingering. Because of the inability of PFTs and other tests to be perfectly sensitive in diagnosing organic

causes of impairment, the diagnosis of malingering should be made with caution. The *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (DSM-5), classifies malingering as a condition “that may be a focus of clinical attention.”⁴⁴ Furthermore, malingering is described as “the intentional production of false or grossly exaggerated physical or psychological symptoms, motivated by external incentives.” Specific listed examples of these external incentives include avoiding work and obtaining financial compensation. The DSM-5 recommends that malingering should be strongly suspected if any combination of the following is noted: (1) there is a medicolegal context of presentation, (2) a marked discrepancy between the person’s claimed stress or disability and the objective findings is noted, (3) a lack of cooperation during the diagnostic evaluation and compliance with the prescribed treatment regimen are observed, and (4) there is the presence of anti-social personality disorder. Malingering is differentiated from a factitious disorder in that the motivation for the symptom production is external, rather than an intrinsic need to maintain the sick role. Malingering may also be differentiated from conversion disorder and other somatoform disorders by the intentional production of symptoms and the obvious external incentives associated with it.

Although it is important to identify frank malingering, which represents fraud, it must be emphasized that malingering is relatively rare and should remain a diagnosis that is made through exclusion and with extreme caution.

MAJOR STATE AND FEDERAL BENEFIT AND COMPENSATION PROGRAMS

Most impairment and disability evaluations will be performed under the context of a particular state or federal program. A number of different programs exist for individuals and workers in specific employment settings. Some of the larger programs include the Federal Black Lung Program for coal mine workers, Social Security Disability for disabled workers, Workers’ Compensation for ill and injured workers through their employers, the Veterans Administration for veterans with service-related conditions, the Energy Employees Occupational Illness Compensation program for Department of Energy workers, with special provisions for workers with chronic beryllium disease and certain workers with silicosis and a defined set of cancers. The *Radiation Exposure Commission Act* (RECA) provides compensation to individuals who develop specific cancers and other serious diseases as a result of exposure to radiation during above-ground nuclear weapons testing or during work as uranium miners, millers, and ore transporters. Most of these programs refer to both impairment and disability. In some programs, the primary determination to be made by the physician is disability, usually in the context of making the dichotomous determination of “disabled” or “not disabled,” and in others the primary determination is impairment. Each system has its own rules by which to establish patient eligibility and rules for assignment of disability and/or impairment. Most major compensation systems require physicians to undergo special training and/or approval

before they are permitted to perform these evaluations for benefits programs.

Detailed descriptions of these programs are contained in the online version of this chapter on ExpertConsult.

WORKPLACE PROTECTIONS

RESPIRATORY PROTECTION

In considering whether respiratory protection may be required in the workplace, it is important to consider NIOSH’s recommended hierarchical approach to reducing workplace exposures including (1) elimination; (2) substitution; (3) engineering controls, such as improving ventilation or enclosing exposures; (4) administrative controls; and (5) as a last resort, personal protective equipment such as respirators.⁵⁶ Medical clearance for the use of respirators is mandated by the OSHA, either through use of their standard questionnaire or through a comparable medical examination.⁵⁷ Before using a respirator, the worker should undergo tests with the specific make and model of the respirator to be used to ensure proper fit and protection. Fit testing is also regulated by OSHA.

WORK RESTRICTIONS

Some compensation systems, such as workers’ compensation, require a statement on ability to work and whether there are any physical activities or exposures the worker should avoid. Treating physicians may recommend temporary work restrictions for their patients during exacerbations of illness; these restrictions may or may not be accommodated by the workplace because there is no requirement for them to do so. Physicians may also assign permanent work restrictions, which employers are obligated to consider for reasonable accommodation under the *Americans with Disabilities Amendments Act* (ADAAA).⁵⁸ Restrictions may include limitations in the ability to perform a specific physical activity, perform it safely on a sustained or repeated basis, and/or to be able to work in the presence of certain dust, fume, gas, chemical, and/or antigen exposures, as in the case of occupational allergic asthma and hypersensitivity pneumonitis.

In order for the physician to determine whether or not the worker can perform job tasks and if restrictions are needed, both the physical requirements of the job and the worker’s capabilities need to be ascertained. Exercise testing, with its limitations noted previously, is a standard approach used in this assessment. Although submaximal testing has been used and does have some advantages in terms of administration and merits in terms of demonstrating a worker’s ability to sustain activity at a predetermined level of exertion, maximal exercise testing is normally used. Accuracy of exercise testing to predict functional performance can be increased by combining exercise testing with measures of pulmonary function³⁶ and with heart rate monitoring during the performance of work activities.⁵⁹ Actual simulation of work may be performed by a physical or occupational therapist, called a *functional capacity evaluation* (FCE). Interpretation of results and formulation of formal work restrictions should be performed in a manner

APPORTIONMENT AND FUTURE MEDICAL TREATMENT

APPORTIONMENT

When multiple disease processes are present that may contribute to respiratory impairment, the physician may be asked to apportion, or make a statement of the relative contribution of each disease process to the total impairment. This is usually performed in the context of workers' compensation in an effort to limit the amount of the monetary award to that specifically attributed to the workplace exposure or event. It does not typically reduce medical treatment benefits or wage compensation. Unfortunately, the scientific basis for this level of precision is rarely present and thus must be acknowledged as arbitrary even if required by the entitlement system.

Cigarette smoking and its sequelae is the most common condition taken into account when considering apportionment of respiratory impairment. For example, much has been written about the difference in symptoms and physical limitations in smoking compared with nonsmoking asbestos workers,⁴⁵ and the observation that the most common cause of exercise limitation in one group studied was the cardiovascular system rather than the respiratory system.⁴⁶ Specific methods for apportionment have been proposed,⁴⁷ but none has been validated scientifically or considered generally accepted. If objective evidence of prior impairment exists, such as diagnostic testing results performed before the work-related exposure or development of disease, some states will allow apportionment to be performed by subtracting the preexisting impairment from the current total impairment.

EXPECTED FUTURE MEDICAL TREATMENT

A description of the expected natural history of the condition, that is, if the condition is expected to remain stable or potentially to deteriorate over time, should be provided. In addition, the recommended medical follow-up and anticipated treatment requirements can provide a helpful measure of reasonably anticipated future medical expenses. This is of value to the worker, as well as insurance adjusters and attorneys.

Most programs include both impairment and disability. In some programs, the primary determination to be made by the physician is disability, usually in the context of making the dichotomous determination of "disabled" or "not disabled." Other systems require the physician to determine impairment. Most major compensation systems require physicians undergo special training and/or approval before they are permitted to perform these evaluations for benefits programs. A few of the larger programs are reviewed in the following sections.

PROGRAMS IN WHICH PHYSICIANS PRIMARILY DETERMINE DISABILITY

Some programs provide benefits to individuals who are determined to be unable to work due to a medical condition. The role of the physician is to determine if there is evidence

of an illness and, if so, to provide medical evidence that supports the determination that the worker cannot engage either in a particular occupation or in any type of gainful employment. These are typically all or none systems; either the worker is totally disabled due to the condition or he or she is not. No benefits are awarded unless the worker is determined to be totally disabled.

Federal Black Lung Program

The Federal Black Lung Program is a medical treatment program for miners, administered through the *Department of Labor* (DOL).⁴⁸ It arose out of the Federal Coal Mine and Safety Act of 1969, with amendments made in 1977, 1981, and 2000. The Act established mandatory safety and health standards in mines and included provisions for research and training. Title IV of the Act established black lung benefits, recognizing that there are many coal miners who are disabled or deceased because of mining-related lung disease, primarily pneumoconiosis. The amendments that followed the initial act broadened the scope of workers covered and the breadth of lung diseases covered. A *miner* is now defined as "any person who works or has worked in or around a coal mine or coal preparation facility in the extraction, preparation or transportation of coal, and any person who works or has worked in coal mine construction or maintenance in or around a coal mine or coal preparation facility." In addition, the amendments also broadened the disease covered, so *pneumoconiosis* is now defined as any "chronic dust disease of the lung and its sequelae including respiratory and pulmonary impairments, arising out of coal mine employment." Thus, the Federal Black Lung program covers not only coal miners with silicosis or coal workers' pneumoconiosis but also airway disease due to coal mining, such as chronic airway obstruction.

Benefits are awarded to the miners or to their *surviving dependents*, defined as the wife or dependent child, parents, or siblings of the miner. Each miner who applies for benefits is afforded the opportunity to undergo a medical evaluation paid for by the DOL to ascertain if she or he is eligible for benefits. The testing must be performed in the manner outlined in the Federal regulations. Only physicians who have been approved by the DOL may perform the examination; they cannot be related to the miner or have examined or treated the miner within the preceding 12 months. Miners may apply for benefits under state workers' compensation as well.

There are strict eligibility requirements. This normally requires the miner to have been employed for a minimum of 10 years in underground mine work. Once determined to be eligible to perform the examination, the physician must then determine if the miner has lung disease due to mining, as defined by the statute. This is most commonly determined on the basis of chest radiograph findings of pneumoconiosis, specifically large or small opacities of profusion 1/0 or greater, read by a NIOSH-certified B-reader, and classified according to the ILO's classification system.²⁰ A determination may also be made by biopsy or autopsy evidence of pneumoconiosis, or through a reasoned medical opinion that there was a condition that would be reasonably expected to yield the previously discussed chest radiograph or pathology findings. The regulations also specify criteria for posthumous determinations.

The physician then determines if the miner meets the definition of *totally disabled*, defined as being unable to work

as a miner or perform comparable work due to respiratory impairment. The medical criteria that establish total disability are pulmonary function test results with FVC, FEV₁, or MVV below values listed in the tables contained in the regulations (60% of predicted), FEV₁/FVC ratio 55% or less, or arterial blood gas analysis based on a PO₂ at or below a value specified for concurrently measured PCO₂, listed in one of three tables provided for different ranges of altitude. If these criteria are met, the physician must also establish that the miner is unable to perform his or her usual job in the coal mine or is unable to be employed in the area of their residence with the skills used in the mines over a period of time. The specific tables noted previously may be accessed at the U.S. DOL's Division of Coal Mine Workers' Compensation page⁴⁹ through the Pulmonary Functions Standards and Tables link. This website also contains a link to the specific standards that must be used for the administration and interpretation of PFTs contained in the legislation.

If not covered under state workers' compensation, medical treatment expenses for black lung–related conditions, including medication, will be covered. Home oxygen, pulmonary rehabilitation, and home health care may be covered after special approval.

Social Security Disability

Amendments to the Social Security Act in 1950 established the first legislation for financial assistance “to aid the permanently and totally disabled.” Numerous changes in this

system have been implemented since that time. The *Social Security Administration* (SSA) oversees two programs: the *Social Security Disability Insurance* (SSDI) program, which pays monthly cash benefits to former workers now unable to work for at least a year due to disability; and the *Supplemental Security Income* (SSI) program, which provides benefits to disabled persons who meet financial need criteria. Former workers are eligible for SSDI if they have earned a sufficient number of work credits while working in the past, based on past contributions made to Social Security. What constitutes a credit is variable, as is number of credits required, and with workers aged 62 years or older requiring the greatest number of credits to qualify.

In this program, the physician must first determine whether an applicant is disabled. *Disability* is defined as not being able to do any substantial gainful work activity because of a medically determined physical or mental impairment, which is expected to last at least 12 months or which may result in death. The determination may be made on the basis of information submitted by treating physicians and/or through an evaluation by an approved physician. There are strict eligibility criteria. The categories of impairments of the respiratory system and an overview of the impairment criteria are listed in [eTable 28-1](#). The SSA outlines the specific tests and testing criteria, including quality considerations, which form the basis for the determination as to whether or not the degree of impairment would be expected to prevent an individual from

eTable 28-1 Social Security Administration Respiratory System Impairment Categories and Criteria by Which to Establish Sufficient Impairment to Result in Disability

Category		Impairment Rating Criteria to Establish Disability
Chronic pulmonary insufficiency	Obstructive disease, any cause	Based on FEV ₁ in liters (BTPS) and height without shoes (Table I)*
	Restrictive disease, any cause	Based on FVC in liters (BTPS) and height without shoes (Table II) [†]
	Pulmonary disease causing gas exchange abnormality	DL _{CO} <10.5 mL/min/mm Hg, or DL _{CO} <40% predicted, or ABG result based on PO ₂ for a specified PCO ₂ , at rest or steady state exercise ≤5 METS [‡]
Asthma		Based on Table I criteria or based on frequency of attacks [§]
Cystic fibrosis		As per COPD or based on frequency of infections or exacerbations or based on infection treatment requirements
Pneumoconiosis		Based on Table II criteria
Bronchiectasis		Based on Table II criteria or based on frequency of infections or exacerbations [§]
Mycobacterial, mycotic, or other chronic infection		Based on Table II criteria
Cor pulmonale	Secondary to pulmonary vascular hypertension	Mean pulmonary artery pressure > 40 mm Hg Arterial hypoxemia [‡] or based on Section 4.02 (chronic heart failure)
Sleep disorders Lung transplant		As per cor pulmonale

ABG, arterial blood gas; BTPS, body temperature, ambient pressure, saturated with water vapor; COPD, chronic obstructive pulmonary disease; DL_{CO}, diffusing capacity for carbon monoxide; FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity; PCO₂, pressure of carbon dioxide; PO₂, pressure of oxygen.

Adapted from the Social Security Administration: Updated Blue Book information can be obtained on the SSA website (<http://www.ssa.gov/disability/professionals/bluebook/>) under the links to the Adult Listings, and the link to Section 3.00 Respiratory system.

*SSA Blue Book Section 3.02 Table I.

[†]SSA Blue Book Section 3.02 Table II.

[‡]SSA Blue Book Section 3.02 Table III-A, III-B, or III-C, depending on altitude.

[§]Frequency of attacks, defined as occurring every 2 months or at least 6 times a year despite treatment. Attacks requiring inpatient hospitalizations are counted as 2 attacks.

^{||}Infection treatment requirements, defined as persistent infection accompanied by bacterial infections occurring at least once every 6 months requiring intravenous or nebulization antimicrobial therapy.

[¶]Frequency of infections or exacerbations, defined as number of episodes of bronchitis, pneumonia, hemoptysis, or respiratory failure requiring treatment occurring at least every 2 months or 6 times per year. Inpatient hospitalizations are counted as 2 episodes.

working. Up-to-date Blue Book information can be accessed freely at the SSA website (<http://www.ssa.gov/disability/professionals/bluebook/>).

PROGRAMS IN WHICH PHYSICIANS PRIMARILY DETERMINE IMPAIRMENT

In addition to the programs outlined previously, some programs compensate workers for permanent impairment remaining after treatment of a medical condition that developed as a direct result of a workplace exposure or activity. A description of a few of these programs follows.

Workers' Compensation

State workers' compensation systems are state specific because they are governed by the rules and laws of each individual state. States began to adopt this European "no-fault" model in the early 1900s in a piecemeal manner.⁵⁰ This system affords employees the right to guaranteed treatment and benefits for an injury or illness that happens "in the course and scope" of their work, regardless of fault, but in exchange for the ability to sue their employers for negligence.⁵¹ The determination that a worker has a work-related condition is usually made by a physician on a medically probable basis (i.e., it is at least 51% likely that work event caused or substantially worsened the condition or illness). Whereas the state workers' compensation systems remain highly variable from state to state, commonalities include employer funding of the system; coverage of medical treatment expenses; temporary wage replacement compensation, usually about two thirds of salary; vocational rehabilitation training (some states only); and compensation for permanent impairment that remains after the worker has completed medical treatment (i.e., is at MMI). There is usually a statute of limitation, or a time period that a claim must be made after the worker has received a diagnosis of a work-related disease. In many states, the statute of limitations is 2 years.

The monies a worker may be paid in compensation for persistent permanent impairment of the respiratory system are usually based on the impairment rating provided by the physician. Most states designate the specific system by which permanent impairment is to be determined. Forty-four states and two commonwealths use the *AMA Guides*.⁶ Some states mandate the use of the "most recent" or "most current" edition, whereas others specifically mandate that a specific edition of the *AMA Guides* be used. Some states, such as Minnesota, have developed their own guidelines for the rating of permanent impairment. Some states, such as Colorado, require that a physician has undergone training and become "accredited" before performing impairment evaluations. Because of the variability of the systems used, as well as concerns for validity and internal consistency within some editions of the *Guides* themselves,⁵² significant variability exists in impairment ratings performed across the country.⁵³ Physicians should consult their state regulations or workers' compensation agencies to learn about the system and statutes used in their state.

There are other workers' compensation programs that cover specific groups of workers. For example, the *Office of Workers' Compensation* (OWCP) administers medical treatment and benefits to current federal workers through the

Federal Employees' Compensation Program, *Department of Energy* (DOE) workers through the EEOICP (as described in the next section), and through the Longshore and Harbor Workers' Compensation Program for workers in these industries. Under the *Federal Employers' Liability Act* (FELA), enacted in the beginning of the 20th century, federal railroad workers must establish that negligence of the railroad or other railroad personnel contributed to the injury or illness through a legal claim before full treatment and other benefits are awarded. If there is "contributory negligence" on the part of the worker, partial benefits are awarded. The Merchant Marine Act (Jones Act) describes a similar system.

Veterans Administration

Department of Veterans Affairs provides medical care for military personnel who have a service-connected condition. Veterans who meet the service requirements and were discharged under other than dishonorable conditions may apply for compensation for disability due to service-connected conditions, defined as injury or illness incurred or aggravated during active military service. Veterans with disabilities can qualify for severance with disability pay or monthly disability compensation. Those veterans who are permanently and totally disabled or 65 years of age and older, had wartime service, and meet the financial eligibility requirement may receive a monthly pension.

Disability ratings are performed according to the Rating Schedule, which contains more than 700 diagnostic codes under 14 different body systems.⁵⁴ Although it is called a disability rating, the listed criteria reflect symptoms, impairment, and treatment requirements by which the rater determines the rating, given in 10% increments ranging from 0% to 100%, rather than a determination of ability or inability to work.

The respiratory system is divided into diseases of the nose and throat, diseases of the trachea and bronchi, and diseases of the lung and pleura. Veterans Affairs-affiliated and Veterans Affairs-designated physicians review medical records and are asked to provide medical history, including current treatment requirements, physical examination findings, and results of diagnostic and clinical tests that support the diagnosis along with any associated conditions, and PFT results. The major criteria that the raters use in the determination of the disability rating for the specified respiratory diseases are shown in [eTable 28-2](#), adapted from the U.S. Department of Veterans Affairs *Web Automated Reference Materials Systems* (WARMS) website, which contains the up-to-date Book C Schedule for Rating Disabilities.⁵⁴ Specific illnesses and medical conditions are presumed to be service connected for select groups of veterans, including prisoners of war, veterans exposed to radiation, Vietnam veterans exposed to agent orange or other herbicides, and Gulf War veterans. These veterans are eligible for disability compensation for those conditions without burden of proof.

ENERGY EMPLOYEES OCCUPATIONAL ILLNESS COMPENSATION PROGRAM

This is a federal program available as an adjunct or alternative to state workers' compensation for workers who were or are employed by or were subcontractors at DOE sites or

eTable 28-2 Veterans Administration: Specific Lower Respiratory Diseases for Which Veterans May Be Eligible for Service-Related Disability and General Criteria Used

Disease	Rating Based on the Following Criteria
Bronchitis, chronic	FEV ₁ , FEV ₁ /FVC, DL _{CO}
Bronchiectasis	Cough frequency, number and frequency of infections requiring antibiotics and incapacitating episodes per year
Bronchial asthma	Frequency and type of treatment, physician visits, severity of attacks, FEV ₁ , FEV ₁ /FVC
COPD, emphysema	FEV ₁ , FEV ₁ /FVC, DL _{CO} , $\dot{V}O_{2max}$ (with cardiorespiratory limit), use of oxygen, evidence of secondary cardiovascular dysfunction*
TB	Active vs. inactive disease, respiratory status, x-ray findings, residual lung disease, thoracoplasty
Pulmonary vascular disease	Pulmonary embolism with residual symptoms, ongoing treatment needs, IVC surgery, evidence of secondary cardiovascular dysfunction*
Neoplasm	If in remission 6 months after ending treatment, rating will be reassessed and may decrease from 100% on the basis of residuals.
ILD†	FVC, DL _{CO} , $\dot{V}O_{2max}$ (with cardiorespiratory limit), evidence of secondary cardiovascular dysfunction,* use of oxygen
Mycotic lung disease‡	Active vs. inactive disease, respiratory symptoms, constitutional symptoms
Restrictive lung diseases§	FEV ₁ , FEV ₁ /FVC, DL _{CO} , $\dot{V}O_{2max}$ (with cardiorespiratory limit), use of oxygen, evidence of secondary cardiovascular dysfunction*
Sarcoidosis	Radiographic involvement, frequency and type of treatment, cardiac involvement, respiratory and systemic symptoms
Sleep apnea	Sleep study results, symptoms, CPAP treatment, respiratory failure

*Evidence of secondary cardiovascular dysfunction: evidence of cor pulmonale, RVH, or pulmonary hypertension.

†ILD: diffuse interstitial fibrosis, DIP, pulmonary alveolar proteinosis, drug-induced pulmonary pneumonitis and fibrosis, radiation-induced pulmonary pneumonitis and fibrosis, HP, pneumoconiosis (silicosis, anthracosis), asbestosis.

‡Mycotic lung disease: histoplasmosis, coccidioidomycosis, blastomycosis, cryptococcosis, aspergillosis, mucormycosis.

§Restrictive lung diseases: diaphragm paralysis/paresis, spinal cord injury with respiratory insufficiency, chest wall deformities, postsurgical residua, chronic pleural fibrosis or effusions.

COPD, chronic obstructive pulmonary disease; CPAP, continuous positive airway pressure; DIP, desquamative interstitial pneumonia; DL_{CO}, diffusing capacity for carbon monoxide; FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity; HP, hypersensitivity pneumonitis; ILD, interstitial lung disease; IVC, inferior vena cava; RVH, right ventricular hypertrophy; TB, tuberculosis; $\dot{V}O_{2max}$, maximal oxygen consumption.

Veterans Affairs Web Automated Reference Materials Systems (WARMS) website: http://www.warms.va.gov/regs/38CFR/BOOKC/PART4/S4_97.DOC (Accessed June 15, 2008).

who worked for businesses that functioned as vendors providing services or goods for the DOE. The compensation program is outlined in the EEOICP Act of 2000, as amended (EEOICPA or Act), which also established the DOL's responsibility for the administration of this program.⁵⁵ Part B of the Act provides compensation to current and former workers who meet DOL criteria for beryllium sensitization, *chronic beryllium disease* (CBD) and silicosis (eTable 28-3). Individuals with beryllium sensitization are awarded medical monitoring for possible progression to CBD, whereas those with CBD and silicosis are awarded medical evaluation to follow up and monitor disease, as well as coverage of medications and consequential illness evaluation and treatment as needed, along with a one-time lump-sum payment of \$150,000.

DOE employees, contractors, and subcontractors and atomic weapons employees diagnosed with cancer are compensated in a manner similar to that of CBD and silicosis, if that cancer is determined to have developed as a result of working at a covered facility, based on DOL criteria. Members of special cohorts, composed of workers at specific sites during certain time periods, are afforded compensation for specific cancers without further burden of proof. The *Radiation Exposure Commission Act* (RECA) provides compensation to individuals who develop these specific cancers and other serious diseases as a result of exposure to radiation during above-ground nuclear weapons testing or during work as uranium miners, millers, and ore transporters.

Eligibility is largely determined on the basis of having worked in certain locations during specified periods of time, a minimum duration of exposure, and having a specific type of cancer. A lump-sum payment and medical expenses will be awarded to individuals who have been awarded compensation by the *Department of Justice* (DOJ). Because the DOL makes the final determination as to whether or not the worker meets the requirements for the diagnosis, the evaluating physician should clearly document the history of the claimed illness(es), physical examination findings, the clinical testing data supporting the diagnosis, and the date the illness was first documented. Consequential illness or injury may be accepted if sufficient medical documentation of its relationship to the covered illness is submitted. There are provisions for survivor eligibility provided as part of this compensation program.

The EEOICP Act established Part E and replaced Part D, a program that had been administered by the DOE in which panels of physicians made medical determinations as to whether or not a particular illness was related to DOE work. Under Part E, DOE employees, contractors, and subcontractors, as well as eligible RECA claimants, are awarded payment of medical expenses, as well as a maximum of \$250,000 compensation for permanent impairment and loss of wages, if they are determined to have developed an illness as a result of occupational exposure to a toxic substance at a covered DOE facility. Workers with conditions accepted under Part B will be automatically accepted under

eTable 28-3 EEOICPA Part B Requirements for Eligibility and Diagnosis under the Act for Beryllium-Related Illness and Silicosis*

Condition	Eligible Workers	Requirements for Diagnosis under Part B
Beryllium sensitization	See chronic beryllium disease	Abnormal <i>Beryllium Lymphocyte Proliferation test</i> (BeLPT) performed on blood or BAL cells
Chronic beryllium disease	Employees of the DOE, its predecessor agencies, contractors, and subcontractors; designated atomic weapons workers; and beryllium vendors	For diagnoses made on or after 1/01/1993 [†] An abnormal BeLPT and at least 1 of the following: 1. Lung biopsy showing a process consistent with CBD 2. A CT scan showing changes consistent with CBD 3. A pulmonary function or exercise tolerance test showing pulmonary deficits consistent with CBD
Chronic silicosis	DOE employee or contractor who worked at least 250 days in underground tunnel operations at the Nevada or Alaska nuclear test sites	One of the following: 1. A chest radiograph B-reading confirming pneumoconiosis with a profusion score of 1/0 or greater 2. Results from a CT or other imaging study consistent with silicosis 3. A lung biopsy consistent with silicosis

*The final decision as to whether or not the patient meets the requirements is made by the Department of Labor.

[†]If the diagnosis was made before 1/01/1993, at least 3 of the following must be documented: characteristic chest radiograph or CT scan denoting abnormalities; a test showing restrictive, obstructive, or diffusion abnormality; lung pathology consistent with CBD; a clinical course consistent with a chronic respiratory disorder; an immunologic test showing beryllium sensitivity (skin patch test or beryllium test preferred).

BAL, bronchoalveolar lavage; CBD, chronic beryllium disease; CT, computed tomography; DOE, U.S. Department of Energy; EEOICPA, Energy Employees Occupational Illness Compensation Program Act.

Adapted from U.S. Department of Labor Medical Requirements under the Energy Employees Occupational Illness Compensation Program Act OMB No. 1215-0197 Expiration date: 08/31/2010 Form EE-7 April 2005.

Part E for compensation for impairment. Unfortunately, DOE vendors are eligible under Part B but are not eligible for compensation under Part E. There is survivor eligibility provided under Part E. Impairment ratings may be performed by physicians who are certified by the *American Board of Independent Medical Examiners* (ABIME) or *American Academy of Disability Evaluating Physicians* (AADEP) or who are otherwise considered by the DOL to have the requisite experience or knowledge. Not all physicians approved to provide care for workers under Part B of the program are eligible to provide impairment ratings under Part E.

Physicians will be asked to submit such credentials for approval by the DOL to confirm their ability to provide impairment ratings. Alternatively, medical consultants to the DOL may perform the ratings. Currently, the ratings are still performed under the *AMA Guides*, Fifth Edition, which had been the most recent edition at the time the legislation was passed. Each percent whole-person impairment determined through an impairment rating is compensated \$2500. Compensation for lost wages is based on the number of years that the employee was unable to work or sustained a reduction in wages because of the illness up to age 65.

consistent with the ADAAA considerations, including suggesting possible methods of reasonable accommodation in the workplace.

AMERICANS WITH DISABILITIES ACT AMENDMENTS ACT

The *Americans with Disabilities Act* (ADA) of 1990 and the *Americans with Disabilities Act Amendments Act* (ADAAA) of 2008 prohibit discrimination against a qualified individual with a *disability*, defined as “a physical or mental impairment that substantially limits a major life activity.”^{58,60} The Act applies to individuals who have, have a record of, or are regarded as having a physical or mental impairment. Initially, determination of whether cases met the ADA criteria focused on whether or not the individual met the definition of disabled. More recently, by retaining the original definitions of disability, the ADAAA expanded the definition of “major life activities” to include activities such as sleeping, standing, lifting, bending, concentrating, communicating, thinking, and working and effectively expanded the number of workers who qualify for coverage under the Act.⁵⁸ A list of “major bodily functions” is also now covered by the ADAAA, such as functions of the immune system, normal cell growth, and respiratory. A disease that causes intermittent impairment or that is in remission is considered a disability if it would substantially limit a major life activity when active. The goal of these changes was to focus workplace accommodation for “qualified individuals.” A qualified individual is a person who has the requisite skills and experience to do the job and “can perform the essential job tasks with or without reasonable accommodation” without risk of direct threat to self or others. Knowing what the essential job tasks are and what is required to do them physically is essential for the physician to be able to make this determination. This information is often contained in the workers’ position description. The worker’s job title typically provides insufficient information.

Essential job tasks are defined as the specific functions that an individual in that position must be able to perform without aid or with the assistance of reasonable accommodation. Factors involved in determining whether or not a job activity is an “essential function” include whether or not all employees in the position are required to perform the task, the position exists to perform the function, the frequency and duration of the job function, and whether or not there are other employees available and qualified to perform the function. A “preemployment” physical is not permitted under the ADA; an employer may not ask questions about disability or require a medical examination until after a conditional job offer has been made. A postoffer, preplacement medical evaluation is permitted, as long as the employer does this for all employees entering the same job category; if doing so is job related and consistent with business necessity on the basis of objective evidence that a worker will be unable to perform essential job functions or will pose a direct threat because of a medical condition; or when an employer receives a request for reasonable accommodation and the disability or the need for the accommodation is not obvious.

Reasonable accommodation is defined as a modification or adjustment to the job, work environment, or way things are

usually done that enables a person with a disability to perform the essential job function. Physicians may suggest means by which reasonable accommodation may be made, but the employer decides whether or not the accommodation is reasonable on a case-by-case basis. Examples of reasonable accommodation for individuals with respiratory impairment can include modification of the workstation to allow use of a wheelchair, scooter, or oxygen equipment; decreasing the need to travel distances, lift or push objects; and/or allowing written rather than lengthy verbal communication. A direct threat exists when an individual poses a significant risk of substantial harm to the health or safety of herself, himself, or others and the risk cannot be reduced to an acceptable level with reasonable accommodation. The risk needs to be defined in terms of the specific behavior or physical limitation that would pose the direct threat, the duration of the risk, the nature and severity of the potential harm, and the likelihood and imminence of the potential harm. An example of direct threat would be use of oxygen in an area with open flames or sparking materials.

FAMILY AND MEDICAL LEAVE ACT

The *Family Medical Leave Act* (FMLA) entitles eligible employees up to 12 weeks of unpaid leave with benefits per year due to a serious health condition of their own or to care for a spouse, child, or parent with a serious health condition.⁶¹ There are additional provisions for child care and service members and their families. Eligibility is based on the number of hours the patient has worked for the employer and the size of the employer. Physicians must complete a standardized form indicating the condition and the expected frequency and duration of the work absences.

FUTURE DIRECTIONS

DEVELOPING AN IMPROVED FRAMEWORK OF DISABILITY

International Classification of Functioning, Disability, and Health

The WHO’s ICIDH model was recognized as problematic in a number of respects, including an implied unidirectional relationship from impairment to handicap, limited definition of the role of the environment, and focus on the disability, rather than the factors that may enable functional ability. The WHO put forth the *International Classification of Functioning, Disability, and Health* (ICF) in 2001 in two parts,⁴ designed to be used in conjunction with the *International Classification of Diseases* (ICD)-10 codes as a uniform description of health and well-being.

The first part of the ICF is most relevant to most physicians, combining consideration of body structure and function, activities, and participation into a unified concept. The term *functioning* according to the ICF combines the positive aspects of body functions, activities, and participation, whereas the term *disability* is used to describe the combination of the negative aspects of functional loss (impairment), activity limitation (disability), and participation restriction (handicap). Part 2 of the ICF describes Contextual Factors,

divided into personal factors, such as age, education, attitudes, and environmental factors. *Facilitators* are contextual factors that enhance functioning and *barriers* are contextual factors that restrict or limit functioning.

This model was developed as a method to describe functioning and disability in a uniform manner across a wide range of medical disorders on an international level. *The World Health Organization Disability Schedule 2.0* (WHODAS 2.0) is an interviewer-administered questionnaire designed to measure functioning and disability within the conceptual framework of the ICF.⁶² It measures six domains (cognition, mobility, self-care, getting along, life activities, and participation). The data are subjective and many of the questions relate to basic ADLs. This tool is not in use in the occupational setting at this time.

INSTITUTE OF MEDICINE FRAMEWORK

An alternative framework to the WHO's ICIDH and ICF models was based on an *Institute of Medicine* (IOM) model that includes pathology, impairment, functional limitation, and disability.^{63,64} The IOM's most recent report *Future of Disability in America* (2007) indicates that the model is still in the process of refinement,⁶⁵ incorporating concepts from other models to emphasize that enablement/disability is a multistage and bidirectional process and that the patient's environment plays a critical role in either facilitating or obstructing functioning and participation.⁶³⁻⁶⁶ In addition, this model incorporates the notion that prevention of conditions arising secondary to the primary condition can improve quality of life.⁶⁵ In the current IOM framework, *pathology* is defined as the "interruption or interference of normal bodily processes or structures caused by disease, trauma, or other conditions." *Impairment* is defined as "loss and/or abnormality of mental, emotional, physiological, or anatomical structure or function." *Functional limitation* is defined as the "restriction or lack of ability to perform an action or activity in the manner or within the range considered normal that results from impairment." *Disability* is defined as the "inability or limitation in performing socially defined activity and roles expected of an individual within a social and physical environment" and expands the definition to the "gap between a person's capacities and the demands of relevant, socially defined roles and tasks in a particular physical and social environment."⁶³ The IOM has indicated that priority should be given to disability research, improving access to health care and support services, reducing barriers to health insurance, making needed assistive services and technologies more available, and developing educational programs and public health campaigns to increase public and health care professionals' awareness of available assistive and accessible technologies.⁶⁵

DISEASE-SPECIFIC IMPAIRMENT

There is increasing recognition that some diseases not only alter lung structure and/or function but also impair other organ systems that in turn contribute to whole-person impairment and disability.^{67,68} COPD is one of the major causes of respiratory impairment and disability,⁶⁹ and the disease has major economic and societal impact world-

wide.⁷⁰ In addition to lung function, COPD impairs lower extremity strength,^{71,72} balance,^{71,73} and cognition⁷⁴ and increases anxiety and depression.^{75,76} This multisystem impairment may arise independent of lung function,⁷⁷ and contribute to decreased global functioning.^{77a} Although this bidirectional relationship is consistent with the IOM framework, it adds considerable complexity to the development of a model through which to estimate impairment and disability caused by a work-related lung disease.

Key Points

- *Impairment* refers to the degree of loss of normal use or function of a body part or organ.
- *Disability* refers to any resulting alteration in the individual's capacity to perform customary activities. That definition has been expanded by the Institute of Medicine to include the "gap between a person's capacities and the demands of relevant, socially defined roles and tasks in a particular physical and social environment," emphasizing the bidirectional nature of the model and the importance of factors in the environment that facilitate or present obstacles to functioning and participation.
- *Maximum medical improvement* (MMI) is the time at which permanent impairment can be assessed. It is achieved when the diagnosis has been well defined, the condition is stable, and medical treatment has either optimized or reasonable options have been exhausted.
- The *Americans with Disabilities Amendments Act of 2008* greatly expanded the definition of disability to focus on workplace accommodation of "qualified individuals." A qualified individual is a person who has the requisite skills and experience to do the job and "can perform the essential job tasks with or without reasonable accommodation" without risk of direct threat to self or others.
- *Reasonable accommodation* is defined as a modification or adjustment to the job, work environment, or the way things are usually done that enables a person with a disability to perform an essential job function.
- An *impairment evaluation* is a medical evaluation that typically includes history, including a detailed occupational and environmental history and description of limitations in activities of daily living; physical examination; and review of medical records and diagnostic test results that establish the respiratory condition. If the worker is at MMI, a permanent impairment rating can be performed. The physician may be asked to address causation, which is usually the disease relationship to workplace exposures, the need for work restrictions, future medical needs, and possibly apportionment of impairment.
- An *impairment rating* is a numeric value from 0% to 100% that represents the percent loss of total body function due to the respiratory system. This numeric value helps form the basis for the monetary award given to workers with permanent impairment that remains after reaching MMI.

- In addition to state and federal workers' compensation programs, other special benefit and compensation programs exist for certain groups of workers, including miners, Department of Energy workers, veterans, and radiation-exposed workers.

INTRODUCTION

Dyspnea (Greek *dys*, meaning “painful,” “difficult,” and *pneuma*, meaning “breath”) is a clinical term for the sensation of breathlessness or shortness of breath experienced by both normal subjects and patients with diseases affecting the respiratory system. Its importance has been recognized by the release of an updated American Thoracic Society Statement.¹ Dyspnea assumes clinical significance when it is felt at a level of exertion that is unacceptably low for the individual or modifies a patient’s lifestyle dramatically in an effort to avoid breathing discomfort. It is increasingly regarded as an important outcome for both prognostic and therapeutic purposes across a wide range of clinical conditions, principally *chronic obstructive pulmonary disease* (COPD),² heart failure,³ advanced cancer,⁴ and interstitial lung diseases.⁵

There are no precise data on the prevalence of dyspnea.⁶ A meta-analysis suggests a worldwide prevalence of 10% for COPD in adults older than 40 years,⁷ making its cardinal symptom, dyspnea, a substantial cause of morbidity, espe-

cially in older people. A high prevalence of dyspnea due to all causes is indicated by a survey of 4900 middle-aged and older adults in which 27.2% reported having dyspnea, whereas only 12.5% reported having COPD.⁶ In a survey of 1556 seriously ill patients admitted to hospital, 49% reported having dyspnea compared with 51% who reported pain.⁸ Morbidity associated with dyspnea is variable, ranging from minor annoyance to functional incapacity.⁹ Moreover, dyspnea is a strong independent predictor of mortality in COPD,¹⁰ heart failure¹¹ and aging.¹² Compared with pain, dyspnea is relatively refractory to effective symptom management, likely affecting not only patients but also their care providers (including health professionals) during terminal or severe chronic conditions.¹³

Dyspnea encompasses a variety of sensations experienced when breathing feels uncomfortable, labored, and unsatisfying,¹ sensations likely to be linked to discrete physiologic mechanisms.¹⁴ As a symptom, dyspnea can be reported only by the patient and is distinct from objective findings or signs associated with physical examination, such as tachypnea, hyperinflation, and cyanosis. Dyspnea

is multifactorial and, although it results from pathophysiologic events, is likely to be influenced by such factors as psychological state, bodily preoccupation, level of awareness, usual level of physical activity, body weight, state of nutrition, and medications. These many modifying factors may explain the variable correlation between dyspnea ratings and airflow limitation or exercise performance.¹⁴ Because most diseases for which dyspnea is a common symptom are essentially irreversible (e.g., chronic lung disease, heart failure, cancer), effective management of the dyspnea symptom to improve quality of life is a desirable goal.

DEFINITION OF DYSPNEA

Over the years there have been many attempts to define dyspnea, and these have shared a common theme of an uncomfortable perception associated with the act of breathing. However, the more formalized definition given in the consensus statement of the American Thoracic Society is now widely accepted and has provided a sound basis for researchers and clinicians concerned with understanding and managing this symptom.¹ This states: “*Dyspnea* is a term used to characterize a subjective experience of breathing discomfort that is comprised of qualitatively distinct sensations that vary in intensity. The experience derives from interactions among multiple physiological, psychological, social, and environmental factors, and it may induce secondary physiological and behavioral responses.” The American Thoracic Society dyspnea statement also emphasizes that “distinct sensations most often do not occur in isolation,” and that the sensations “vary in their unpleasantness and their emotional and behavioral significance.”¹

LANGUAGE OF DYSPNEA

The breathing discomfort associated with various cardiopulmonary derangements is characterized by a range of words and phrases used to describe the sensation and can trigger strong affective responses. Studies of the language of dyspnea provide insights into the patient's perception of the problem, and these descriptors often offer clues to the underlying physiologic derangements. A multidimensional model for dyspnea, which includes sensory intensity, qualitative descriptors, and affective elements has been proposed.¹⁵

QUALITATIVE PHRASES—THE DESCRIPTIVE DIMENSION OF DYSPNEA

When patients complain of being short of breath, they are usually reporting familiar sensations that have become noticeable at lower levels of exertion. When questioned further, patients may volunteer comments such as “hard to breathe,” “can’t get enough air,” or “feeling tight” but often have difficulty being more specific. Overlaying this, cultural or language differences may result in patients using different words to describe the same sensory experience.¹⁶ Modeled on the proven clinical utility of evaluating the language of pain (e.g., assessing ischemic heart disease),

researchers have asked if the language of dyspnea might be similarly useful.

Since the early 1980s, studies in healthy subjects and dyspneic patients have identified distinctive clusters of descriptors from commonly used expressions of breathing discomfort. In general, four primary categories of breathing discomfort can be identified by the following descriptors: “tightness,” “need or urge to breathe,” (often labeled “air hunger”), “work or effort of breathing,” and “depth and frequency of breathing.” In patient populations, “tightness” appears to be clearly associated with bronchoconstriction, whereas “urge to breathe” is associated with enhanced central drive and/or limitations of tidal volume, and “effort of breathing” is seen in conditions characterized by alterations in the respiratory pump (e.g., ventilatory muscle weakness or increased airway resistance). The “depth and frequency of breathing” descriptor, typically associated with activity or exercise, probably relates more to awareness of chest wall movement than to awareness of breathing discomfort but may nonetheless be worrisome to the patient.

Although there are few cross-cultural studies of the language of dyspnea, the basic categories of phrases noted previously appear consistent across countries.¹⁴ In addition, children use qualitative descriptors to describe the respiratory discomfort associated with asthma in a manner quite similar to adults, and their use of language is reliable over time.¹⁷ Other factors, such as obesity, may be associated with different sensory qualities that relate to the intensity of the breathlessness.^{17a} The primary studies that have defined and explored the utility of qualitative descriptors have been summarized.¹⁴

EMOTIONAL PHRASES—THE AFFECTIVE DIMENSION OF DYSPNEA

The pain model of symptom attributes has been further applied to explore the importance of the affective component (e.g., unpleasantness, fear, anxiety) of dyspnea in addition to its intensity and quality.¹⁵ One study reported that for a given intensity of dyspnea, a stimulus with a greater “air hunger” component is perceived as a substantially more unpleasant experience than one with a strong “work/effort” component.¹⁸ These authors have developed a multidimensional profile for dyspnea, based on an analogous instrument for pain, which should provide a better understanding of the affective component of dyspnea with a view to developing more-targeted therapeutic approaches; reliability and validity of the instrument have been demonstrated.^{18,19} Similar efforts have produced a single dyspnea tool that incorporates both the descriptive and affective dimension into one instrument.^{20,21}

In patients with COPD, those with more severe degrees of respiratory system dysfunction, as evidenced by the BODE (*body mass index, airflow obstruction, dyspnea, and exercise capacity*) index, volunteered more extreme affective phrases, such as “frightening” and “worried.”²² Furthermore, those patients expressing higher dyspnea-related fear may have greater improvements in dyspnea with a pulmonary rehabilitation program.²³ Interestingly, there appears to be no difference in the affective response in patients with COPD when they have dyspnea at home compared to when dyspnea is stimulated in a laboratory setting,²⁴ which

suggests that the ability to control dyspnea by reducing activity may mitigate the emotional dimension in a manner similar to telling an investigator to stop the experiment.

A more careful consideration of the language and emotional impact of dyspnea by health practitioners might yield important diagnostic insights or improved management of breathless patients and is increasingly becoming a marker of quality of care for evaluating dyspnea.²⁵

MECHANISMS OF DYSPNEA

The neurophysiologic mechanisms that give rise to the perception of dyspnea are incompletely understood (Fig. 29-1). Current thinking suggests that the discomfort of dyspnea comprises two primary components: (1) an “urge to breathe” (referred to as “air hunger”) and (2) a “sense of excessive effort” associated with breathing. Although sensations of urge to breathe and effort increase together with exertion, they can be separated experimentally²⁶ with the former being reported as more unpleasant in healthy subjects.²⁷ A third quality of respiratory discomfort, “chest tightness,” is commonly reported by asthmatics.²⁸ Dyspnea in an individual patient may well represent a combination of these component sensations and account for the different qualities of dyspnea mentioned previously.

As with all sensations, the experience of dyspnea must result from changes in neural activity within the cortical and subcortical structures of the brain involved in perception. Respiratory-related afferent information from the upper airway, lungs, thoracic cage, and chemoreceptors as well other signals from, for example, exercising limbs and the cardiovascular system provide numerous peripheral inputs relating to cardiorespiratory function. Such information may integrate with central neural respiratory networks, notably in the cerebral cortex, limbic system, and

brain stem to generate a range of respiratory sensations.²⁹ Moreover, these experiences are likely to be modulated by neural traffic related to cognitive, emotional, and nonrespiratory sensory input. The fact that clinical dyspnea can arise with or without deficiencies in gas exchange and in the presence or absence of impaired respiratory mechanics underscores the complexity of this symptom. As indicated earlier, the use of language to identify qualitative variations in dyspnea, perhaps related to different patterns of central neural activation, may lead to a more comprehensive understanding of the origin of dyspnea and better therapeutic strategies for its management in individual patients.

Because dyspnea is a perception, studies on its mechanisms must be confined to humans and are limited by the difficulty of measuring a subjective experience and the neural activity that underlies it. Neuroimaging technologies, principally PET and functional magnetic resonance imaging, allow imaging of brain function associated with sensory, motor, and cognitive processes, and these have been applied to study the neural basis of dyspnea in healthy subjects. Different investigators have induced dyspnea in different ways, with varying degrees of “urge to breathe” and “sense of effort.” Despite this, a consistent pattern of neural activity associated with dyspnea perception is emerging from these studies. Of particular note is the activation of limbic and paralimbic structures, especially the anterior insular cortex, anterior cingulate gyrus, amygdala, and cerebellum. Activation of these phylogenically ancient regions of the brain has been seen in brain imaging studies of pain,³⁰ thirst,³¹ and hunger³² and is consistent with the idea that dyspnea is a primal experience associated with behaviors intended to counteract a threat to survival.³³⁻³⁵ Such studies are difficult to interpret definitively and are not easily generalizable to clinical populations. Nonetheless, neuroimaging techniques are rapidly becoming more sophisticated, and future studies in symptomatic populations offer the potential of a clearer picture of the neural basis of clinical dyspnea.

There is good evidence that the “urge to breathe” component of the dyspnea sensation depends to a large extent on the degree to which respiratory-related neurons in the brain stem are stimulated. Stimulation of ventilation with exercise, hypoxia, hypercapnia, and metabolic acidosis induces dyspnea,^{36,37} whereas a voluntary increase in ventilation induces little dyspnea, even in patients with respiratory mechanical limitation.³⁸ Moreover, dyspnea is felt strongly when the respiratory neurons are stimulated in the absence of a possible ventilatory response, as with spinal transection and experimental respiratory muscle paralysis.^{39,40} The role of afferent feedback from the lungs and chest wall in the genesis of dyspnea is complex. Conditions thought to activate lung irritant receptors and/or pulmonary C fibers (e.g., pulmonary edema, atelectasis, congestive heart failure) may well contribute to dyspnea via vagal nerve afferents either directly or by modulating other sensory inputs that give rise to dyspnea.^{40,41} Conversely, physiologic activation of slowly adapting stretch receptors during lung inflation may inhibit the central respiratory drive and in this way ameliorate dyspnea. When the desired ventilation and the achieved ventilation are not matched, based on feedback from mechanical and flow (temperature) receptors in the lungs, airways, and chest wall, the intensity

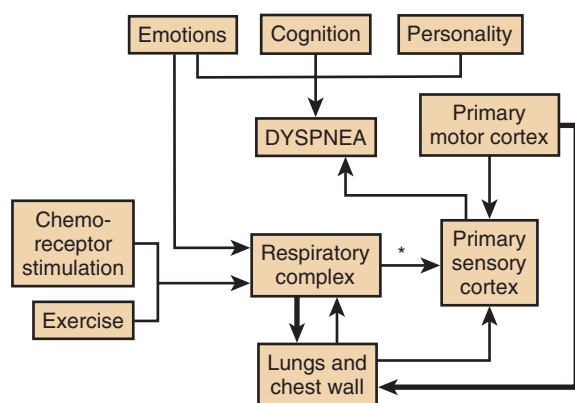

Figure 29-1 The respiratory complex in the brain stem is central to our understanding of dyspnea. Activation of the respiratory complex by afferent input from a variety of receptors or by emotions, with input from the lungs and chest wall, determines the efferent command to the lungs and chest wall to breathe. The brain is made aware of this as dyspnea by a simultaneous corollary discharge (*) to the primary sensory cortex. Alternatively, the primary motor cortex can initiate voluntary efferent commands to the lungs and chest wall to control breathing, with coactivation of the primary sensory cortex, which contributes to dyspnea. The primary sensory cortex also receives input from the lungs and chest wall that may affect the perception of dyspnea. The central experience of dyspnea may also be affected by emotions, cognition, and personality. (Bold lines indicate efferent output commands to the lungs and chest wall to breathe.)

of dyspnea increases. The immediate relief of dyspnea observed with thoracic movements following breath-holding but without improvements in blood gas status is consistent with this concept.⁴²

In their review of the roles of airway nerves in inflammatory airway disease, Undem and Nassenstein⁴⁰ implicate vagal mechanisms in the production of dyspnea, both directly by neural signaling and indirectly by increasing the work of breathing via the release of acetylcholine (which stimulates airway smooth muscle contraction and mucus secretion). Nishino⁴³ suggested that vagal mechanisms associated with coughing affected the sensation of dyspnea, although the author agreed that other neural mechanisms could play roles. Further support for this comes from the observation in quadriplegic patients, who lack afferent information from the chest wall, that increases in tidal volume reduce the dyspnea from carbon dioxide inhalation without any change in blood gas levels.⁴⁴ Moreover, inhaled furosemide, which potentiates slowly adapting stretch receptor activity in an animal model, has been shown to ameliorate the sensation of experimental dyspnea in healthy subjects⁴⁵ and exertional dyspnea in COPD patients.⁴⁶ With respect to “sense of effort,” proprioceptive feedback from muscle, joint, and metaboreceptors (peripheral afferent nerves that respond to metabolic by-products of skeletal muscle metabolism) probably integrates with the motor cortical output in the genesis of this perception.¹⁴

In light of the previous discussion, exertional dyspnea in patients with lung disease can be considered a manifestation of the increased central respiratory drive necessary to achieve adequate ventilation by a mechanically constrained respiratory apparatus. This concept fits with the observation that, in COPD patients, progressive hyperinflation is associated with increasing dyspnea because ventilatory demands require greater respiratory muscle activity to overcome increased elastic work at high lung volumes and to offset the foreshortening of inspiratory muscles that places them at a mechanical disadvantage.^{14,47} Furthermore, to the extent that inspiratory capacity is compromised by increases in end-expiratory lung volume in these patients, expected tidal volume and achieved tidal volume are not matched, and dyspnea intensity increases.^{14,47} Following from this, the lessening of dyspnea that follows successful lung volume-reduction surgery, as well as pharmacologic lung volume reduction,⁴⁷ is consistent with improvement in both lung and respiratory muscle mechanics. Support of this concept comes from a study showing that a decrease in dyspnea after volume reduction was associated with alleviation of hyperinflation of the lungs and a decrease in neural drive to the diaphragm.⁴⁸ Moreover, the concept is supported by the observation that noninvasive ventilatory support during exercise relieves dyspnea in patients with COPD,⁴⁸ presumably by reducing the work of breathing and consequently the efferent neural activity to respiratory muscles.

The utility of this concept of dyspneogenesis extends to conditions in which lung disease is not the primary problem. In particular, the dyspnea of heart failure might be accounted for in terms of a heightened respiratory drive secondary to expiratory flow limitation⁴⁹ or peripheral muscle dysfunction.⁵⁰ A similar phenomenon may arise with deconditioning. The benefits of exercise training for

those with dyspnea may be mediated in part by changes in peripheral muscle function. Other conditions in which dyspnea in the absence of lung disease could be accounted for by increased respiratory drive include motor neuron disease/respiratory muscle weakness,⁵¹ late-stage pregnancy,⁵² anemia,⁵³ thyroid disorders, panic disorder, and anxiety.⁵⁴

The sensation of dyspnea, like pain, has a psychological dimension.⁵⁵ An individual's emotional state, personality, previous experience, and cognitive function are likely to influence the experience and reporting of dyspnea. Dyspnea is worse when it is unexpected, when it happens in inappropriate situations, and when it is perceived by the patient to be dangerous.⁵⁶ Studies in healthy subjects and in patients with underlying disease have suggested that perception of the intensity of breathlessness may be influenced by prior experience of the sensation.^{57,58} Moreover, both auditory distraction⁵⁹ and experimentally induced changes in mood⁶⁰ have been shown to increase the unpleasantness of exertional dyspnea in COPD patients. Whether such observations are related to the frequency of prior experience of dyspnea (e.g., with exercise) or to some ill-defined psychological factor is unknown. In patients with the hyperventilation syndrome, both dyspnea and ventilation may dramatically increase in the absence of any known physiologic stimulus to breathe.⁵⁴ Dyspnea is a particular problem in patients with panic attacks. An Internet-based survey found that 95% of the respondents reported breathing problems during panic attacks, and 68% reported “remarkable” dyspnea.⁶¹ An interesting example of clinically significant activity-related breathlessness in healthy human pregnancy is reported by Jensen and colleagues.⁶² They observed that variability in the perceptual response to exercise could not be explained by variation in central ventilatory drive or in respiratory mechanical/muscular factors, but ultimately reflected a difference in awareness of increased ventilation. The source of that variation in perception is not clear. O'Donnell and coworkers⁶³ have reviewed the role of “higher center” neural processing on dyspnea perception and its relevance to self-management of this symptom.

In sum, dyspnea may develop when there is (1) increased central respiratory drive secondary to exercise, hypoxia, hypercapnia, or other afferent input; (2) augmented requirement for the respiratory drive to overcome mechanical constraints or weakness; and (3) altered central perception.

ASSESSMENT OF DYSPNEA

Clinicians generally rely on a combination of patients' reports and physiologic measurements (e.g., *forced expiratory volume in 1 second* [FEV₁]) to evaluate the presence and intensity of dyspnea and its pathologic origins. By assessing the nature and severity of symptoms, such as dyspnea, physicians quickly gain an advantage in the decision-making process. With a better understanding of the physiologic basis of symptoms, physicians can target the types and extent of diagnostic testing as well as the urgency with which a diagnosis must be made. Understanding the mechanisms of dyspnea or the responses to interventions, however, requires objective measurement of the symptom.

Although primarily used for clinical investigation, there is increasing interest in applying dyspnea measurements to clinical practice.⁶⁴ For a review of factors that limit exercise performance in COPD and the identification of factors that contribute to the variability of dyspnea during exercise, see Stendardi and associates.⁶⁵ O'Donnell and coworkers¹⁴ present a hypothetical model for exertional dyspnea based on current neurophysiologic concepts that were developed to explain the origins of “effort,” “air hunger,” and the accompanying affective “distress” response.

EXERCISE PERFORMANCE AS AN INDICATION OF DYSPNEA

Exercise testing is commonly used to understand dyspnea better,⁶⁶ although there are discrepancies in the available diagnostic algorithms.⁶⁷ This form of testing focuses more on physiologic limitations than on the symptoms that limit exercise and might not be necessary for all patient groups. Two widely used field tests are the 6-minute walk distance and shuttle walking tests,⁶⁸ which are easy to perform and require minimal equipment; more sophisticated cardiopulmonary exercise testing can be particularly helpful when it is unclear whether the patient is limited by the respiratory or the cardiovascular system.^{69,69a} When an exercise test is limited by symptoms, it is important to ask the patient the exact reason for stopping. Although the patient may appear to be in respiratory distress, it is not uncommon that joint pain, leg fatigue or discomfort, or generalized weakness is the actual limiting factor.

EXERCISE LIMITATION DUE TO DYSPNEA

Early attempts to evaluate the severity of dyspnea involved patient assessments of their own exercise tolerance (e.g., the five-point Medical Research Council scale⁷⁰ and its modified version, the American Thoracic Society scale). Although such scales are simple, they are insensitive, require individuals to make comparisons with others, and cannot readily measure changes following therapeutic interventions. The Baseline Dyspnea Index, a rater-administered test, was developed to rate patients with regard not only to the “magnitude of the task” that elicits dyspnea (e.g., hills compared with level ground) but also to the impact of dyspnea on activities of daily living and the effort required to produce dyspnea.⁷¹ Measurements can be repeated over time or in response to interventions. A number of easy-to-use self-administered questionnaires to assess functional limitation due to dyspnea have been developed but in general have not found widespread use.⁷²

QUALITY OF LIFE AND DYSPNEA

The negative impact of dyspnea on an individual's quality of life has been increasingly recognized since the mid-1980s and now is an important outcome measure in studies of therapeutic intervention for COPD/dyspnea. Two questionnaires, the Chronic Respiratory Disease Questionnaire and the St. George's Respiratory Questionnaire, are used most often. The Chronic Respiratory Disease Questionnaire is a rater-administered questionnaire with 20 items that focus on four aspects of illness: dyspnea, fatigue, emotional function, and the patient's feeling of control over the disease.⁷³ Dyspnea is evaluated on a seven-point scale in relation to the five most important activities provoking dyspnea during the previous 2 weeks. In effect, the Chronic Respiratory Disease Questionnaire assesses how breathing sensations alter the quality of the patient's life. The St. George's Respiratory Questionnaire is a self-administered questionnaire with 76 items addressing symptoms, activity, and the impact of disease on daily life. Dyspnea is not evaluated specifically but is included with other respiratory symptoms such as cough, sputum, and wheezing.⁷⁴ These instruments have been shown to be reproducible, to correlate with each other, and to relate appropriately to physiologic measurements.⁷⁵⁻⁷⁷ Although important for clinical investigation, these tools are somewhat demanding to use, often requiring trained health personnel, and are of unproven value for routine clinical care.

PSYCHOMETRIC MEASUREMENT OF DYSPNEA

Several instruments are available for rating the symptom dyspnea directly; they allow reasonably reproducible rating of the intensity of dyspnea on a simple linear or numeric scale during exercise or in response to specific questions. The *visual analogue scale* (VAS) is a horizontal or vertical line, usually 10 cm long, anchored at either end with words such as “no dyspnea” and “maximal dyspnea” (Fig. 29-2). In response to a question (e.g., “How short of breath are you?”), the subject marks a point along the line so the length reflects the intensity of the sensation. The Borg scale is a 10-point scale with extremes of “nothing at all” and “maximal.”⁷⁸ Unlike the visual analogue scale, the Borg scale (Table 29-1) includes verbal descriptors (e.g., “slight,” “severe”) to assist in rating the symptom. Both scales demonstrate good reproducibility,^{79,80} but the proximity of the terms “slight” and “severe” on the Borg scale may reduce its sensitivity and discourage subjects from using the whole scale as they do with the visual analogue scale.⁸¹ A valid approach, which has perhaps better clinical utility, has been

Figure 29-2 Visual analogue scales, such as the horizontal one shown here, can be used for measuring dyspnea during an activity (e.g., exercise testing) or in response to questions. Such scales may be depicted vertically as well. On request, the subject marks a point on the line in response to a question (e.g., How short of breath are you right now?). The score is determined by the length of the line from “no shortness of breath” to the point marked by the patient. The scales are usually 10 cm long to facilitate scoring, and electronic scales may be used to allow online scoring (e.g., during exercise testing). Instructions about what is meant by the terms used to describe a sensation (e.g., “extremely breathless”) must be clear and must be presented in a uniform fashion to provide meaningful results. The description of the “anchors” at each end of the scale must also be clearly defined in terms that are meaningful to the patient or research subject.

Table 29-1 Modified Borg Category Scale for Rating Dyspnea

Rating	Intensity of Sensation
0	Nothing at all
0.5	Very, very slight (just noticeable)
1	Very slight
2	Slight
3	Moderate
4	Somewhat severe
5	Severe
6	
7	Very severe
8	
9	Very, very severe (almost maximal)
10	Maximal

to employ a simple numeric rating scale ranging from 0 to 10.⁸² Additional scales continue to be developed.⁷² Any of these validated instruments may be appropriate when designing research studies, but it is critical that they be administered in a standardized way.

MULTIDIMENSIONAL ASSESSMENT OF DYSPNEA

There has been a growing focus on extending the assessment of dyspnea beyond the intensity domain to include the qualitative and affective components of this complex symptom. Using a multidimensional approach (modeled on those widely used in pain research), there are now a number of validated instruments that are being used in research and clinical studies. A number of these are referenced in the “Language of Dyspnea” section¹⁹⁻²¹ and have been comprehensively reviewed, in the overall context of dyspnea assessment.⁸³

DIAGNOSTIC APPROACH TO THE PATIENT WITH DYSPNEA

OVERVIEW: PHYSIOLOGIC CATEGORIES OF DYSPNEA

The differential diagnosis of dyspnea includes neuromuscular, renal, endocrine, rheumatologic, hematologic, and psychiatric diseases, as well as diseases of the lungs, heart, and chest wall. The diagnostic approach is determined by the acuity of the problem. For acute dyspnea, the differential diagnosis is relatively narrow, and the cause is generally easily identified (e.g., pneumonia, pulmonary embolism, congestive heart failure, asthma), although psychogenic dyspnea or hyperventilation syndrome can pose a diagnostic challenge.⁸⁴ For subacute or chronic dyspnea, a systematic, physiologically based approach enables one to make sense of what otherwise becomes a long list of potential diagnoses.

At its core, the goal of the respiratory and cardiovascular systems is to take oxygen from the air we breathe, transfer it to hemoglobin, deliver it to metabolically active tissue, and transport carbon dioxide, the primary product of

metabolism, back to the lung, where it can be eliminated. Dyspnea arises (1) when this goal has not been met and the patient becomes hypoxemic, hypercapnic, and/or acidemic with consequent stimulation of the chemoreceptors; (2) when achieving this goal produces stress within the cardiorespiratory system (e.g., increased work of breathing, inappropriately small tidal volume for a given level of respiratory drive, or elevated left ventricular and pulmonary capillary pressures, secondary to pathologic abnormalities); or (3) when pulmonary receptors (e.g., irritant receptors, again resulting from a pathologic process) are stimulated. Ultimately, one can consider dyspnea as originating from the respiratory or cardiovascular systems, which includes derangements in oxygen delivery, such as in anemia, and problems with uptake and utilization of oxygen, such as in mitochondrial disorders.

To facilitate a systematic approach to this problem, one can divide the process of respiration into three components (Table 29-2):

1. A controller, which determines the rate and depth of breathing;
2. A ventilatory pump, which facilitates the movement of gas into and out of the alveolus; and
3. A gas exchanger, which consists of the pulmonary vasculature and the alveolus.

Abnormalities in any one of these elements can lead to dyspnea. Similarly, one can consider the derangements of the cardiovascular system within three categories: conditions characterized by high cardiac output, normal cardiac output, and low cardiac output.

Abnormalities of the *controller*, such as any stimulus of ventilation (e.g., exercise, hypoxia, acidosis, interstitial edema, pulmonary hypertension), may provoke the sensation of dyspnea. Diseases that interfere with the *ventilatory pump* increase the effort of breathing, whether because of narrowing of the airway or because of a change in the elastic properties of the lungs or chest wall. If the respiratory muscles are weakened, the effort of breathing seems greater because a larger fraction of maximal available muscle force is required. (This is analogous to peripheral muscle function, in which, for example, it would be more difficult to lift a weight after an arm has just been liberated from being in a cast.) Mechanical derangements of the pump also frequently result in inappropriately small tidal volumes. Patients with reduced chest wall compliance or dynamic hyperinflation, which reduces inspiratory capacity as end-expiratory lung volume approaches total lung capacity, commonly complain of air hunger or an unsatisfied inspiration as a consequence of the limited tidal volume.^{63,85} One study described a change in the qualitative descriptors used by patients with COPD from “work and effort” to “unsatisfied inspiration” as dynamic hyperinflation led to increasingly small tidal volume.⁸⁶ Abnormalities in the *gas exchange* functions can lead to increased respiratory drive and resultant dyspnea. Psychological dysfunction may cause or exaggerate dyspnea and is thought to be an alteration in behavioral control of breathing.⁸⁷ In many conditions the origin of dyspnea is only partially understood (e.g., pulmonary embolism without hypoxemia) or is due to multiple factors (e.g., abnormalities of the ventilatory pump and gas exchange in a patient with COPD).

Table 29-2 Diseases That Cause Dyspnea Grouped by Physiologic Mechanism of Action***VENTILATORY CONTROLLER AND GAS EXCHANGE—INCREASED RESPIRATORY DRIVE****Simulation of Chemoreceptors**

Conditions leading to acute hypoxemia

Impaired gas exchange (e.g., asthma, pulmonary embolism, pneumonia, congestive heart failure[†])

Environmental hypoxia (e.g., altitude, contained space with fire)

Conditions leading to increased dead space and/or acute hypercapnia

Impaired gas exchange (e.g., acute, severe asthma, exacerbations of COPD, severe pulmonary edema)

Impaired ventilatory pump (see below) (e.g., muscle weakness, airflow obstruction)

Metabolic acidosis

Renal disease (renal failure, renal tubular acidosis)

Decreased oxygen-carrying capacity (e.g., anemia)

Decreased release of oxygen to tissues (e.g., hemoglobinopathy)

Decreased cardiac output

Stimulation of Pulmonary Receptors (Irritant, Mechanical, Vascular)[‡]

Interstitial lung disease

Pleural effusion (atelectasis)

Pulmonary vascular disease (e.g., thromboembolism, idiopathic pulmonary hypertension)

Congestive heart failure

Mild asthma

Inhalation of toxic gases

Behavioral Factors

Hyperventilation syndrome, anxiety disorders, panic attacks

VENTILATORY PUMP—INCREASED EFFORT OR WORK OF BREATHING**Muscle Weakness**

Myasthenia gravis, Guillain-Barré syndrome, spinal cord injury, myopathy, postpoliomyelitis syndrome

Decreased Compliance of the Chest Wall

Severe kyphoscoliosis, obesity, pleural effusion

Airflow Obstruction (Includes Increased Resistive Load from Narrowing of Airways and Increased Elastic Load from Hyperinflation)

Asthma, COPD, laryngospasm, aspiration of foreign body, bronchitis

*Some diseases appear in more than one category. They act via several physiologic mechanisms.

[†]Heart failure includes both systolic and diastolic dysfunction. Systolic dysfunction may produce dyspnea at rest and with activity. Diastolic dysfunction typically leads to symptoms primarily with exercise. In addition to the mechanisms noted above, systolic heart failure may also produce dyspnea via metaboreceptors; these are receptors that are postulated to lie in muscles and are stimulated by changes in the metabolic milieu of the tissue that result when oxygen delivery does not meet oxygen demand.

[‡]These conditions probably produce dyspnea by a combination of increased ventilatory drive and primary sensory input from the receptors. COPD, chronic obstructive pulmonary disease.

HISTORY

A comprehensive medical history is important for uncovering the diagnosis responsible for dyspnea.⁸⁸ It is important to identify activities that precipitate it and to understand its impact on the patient's life. Because decreased exercise tolerance may go unrecognized by the patient owing to alterations in lifestyle that do not tax the respiratory and cardiovascular systems (e.g., a patient who develops

dyspnea climbing stairs may move from a two-story house to a single-level apartment), input from close acquaintances may be helpful. Although most patients with severe lung disease report that their activities are limited by dyspnea, some patients are actually more limited by fatigue, weakness, joint pain, or chest pain than by dyspnea. Key questions to ask your patient to localize the cause of exercise limitation include the following: "At the moment you feel you need to stop (walking, jogging, etc.), what is making you stop?" or "If I could fix one thing to enable you to walk more, what would that be?"

The key areas of inquiry are (1) quality of the symptom, (2) persistence or variability of the symptom, and (3) aggravating or precipitating factors leading to the symptom. As noted previously (in "Mechanisms of Dyspnea"), the sensation of "chest tightness" is commonly associated with bronchoconstriction, an increased sense of "effort or work of breathing" is typical of derangements of the ventilatory pump, and a sense of "air hunger" or "urge to breathe" is characteristic of problems that stimulate the respiratory controller (often exacerbated by inappropriately small tidal volume). The sense of difficulty getting a deep breath may be associated with hyperinflation due to obstructive lung disease or with the hyperventilation syndrome.

Intermittent dyspnea is probably due to reversible conditions (e.g., bronchoconstriction, congestive heart failure, pleural effusion, acute pulmonary embolism, hyperventilation syndrome), whereas persistent or progressive dyspnea is more characteristic of chronic conditions (e.g., COPD, interstitial fibrosis, chronic pulmonary embolism, dysfunction of the diaphragm or chest wall). Nocturnal dyspnea may be brought on by asthma, congestive heart failure, gastroesophageal reflux,⁸⁹ obstructive sleep apnea, or even nasal obstruction. Dyspnea in the recumbent position (i.e., orthopnea) is classically associated with left ventricular failure but may also be seen with abdominal processes (e.g., ascites) or diaphragmatic dysfunction. Dyspnea that worsens in the upright position (i.e., platypnea) may be related to orthodeoxia, a decrease in arterial PO_2 in the upright position, seen with cirrhosis, pulmonary arteriovenous malformations, or interatrial shunts.⁹⁰⁻⁹³ Physical activity generally accentuates dyspnea of physiologic origin, as when ventilation is stimulated by lactic acid production at relatively low levels of exercise (e.g., anemia, cardiac disease, deconditioning). Dyspnea after exercise may be affected by a number of factors (e.g., activity, time of day, position, exposures, meals, medications). To the extent that postexercise dyspnea may be mitigated by warm-up activities or use of inhaled bronchodilators, exercise-induced asthma should be considered. Although emotional states may affect dyspnea of any cause,⁸⁴ psychogenic dyspnea should be suspected when dyspnea varies on a daily or hourly basis, especially when it is unrelated to exertion or if litigation is involved.⁸⁷

Recognition of factors that may precipitate (e.g., cigarettes, allergens, smog) or relieve (e.g., position, medications) breathlessness is helpful. Obesity may aggravate dyspnea because of increased metabolic and ventilatory demands as well as mechanical interference with chest movement.⁹⁴ Severe weight loss may weaken the respiratory muscles.⁹⁵ Symptoms of right ventricular failure (e.g., abdominal swelling, edema of the extremities) suggest

hypoxemia, pulmonary vascular problems (e.g., pulmonary hypertension of any cause, obstructive sleep apnea), or left ventricular failure. Neuromuscular diseases, such as amyotrophic lateral sclerosis, may present with dyspnea as a result of respiratory muscle weakness.⁹⁶ Raynaud phenomenon alone or in combination with skin, joint, or swallowing problems suggests collagen vascular disease.

PHYSICAL EXAMINATION

Pattern of breathing (e.g., splinting, use of pursed lips or accessory muscles), body habitus (e.g., cachexia, obesity), posture (e.g., leaning forward on elbows to recruit pectoralis muscles as ventilatory muscles, as in COPD), skeletal deformity, and emotional state may be important clues to the underlying diagnosis. Cough on deep inspiration or expiration suggests asthma or interstitial lung disease. A generalized decrease in the intensity of breath sounds suggests emphysema or moderate to severe bronchoconstriction, whereas a localized decrease may result from pneumothorax, pleural effusion, localized airway obstruction, or elevated hemidiaphragm of any cause. Forced expiratory maneuvers may elicit focal or diffuse wheezing. Cardiac examination may suggest pulmonary hypertension (e.g., right ventricular heave or prominent P₂) or right ventricular failure (e.g., jugular venous distention, right-sided S₃ gallop). Clubbing of the digits is an easily overlooked sign of many processes, notably cancer or purulent lung disease (e.g., bronchiectasis). Cyanosis, a bluish coloration of the perioral region or nails, indicates there are at least 5 g of deoxygenated hemoglobin per 100 mL of blood (note: hypoxemia in the presence of significant anemia may not cause cyanosis because of insufficient hemoglobin). Edema of the lower extremities suggests congestive heart failure if symmetrical and thromboembolic disease if asymmetrical. Assessment of the patient's emotional status may be helpful.⁸⁴

If a patient's history includes a report that he or she develops dyspnea walking a short distance (e.g., <200 yards), one should consider walking the patient in a corridor or up a flight of stairs near the examination room to provoke his or her symptoms. When the patient becomes dyspneic, observe the patient, repeat the vital signs, reexamine the chest and heart, and check the oxygen saturation with pulse oximetry. The development of an abrupt increase in heart rate and blood pressure (e.g., pulse pressure product) or onset of basilar crackles or acute wheezing suggests a rapid increase in pulmonary capillary pressure and interstitial edema. Rapid shallow breathing may be a sign of stiff lungs or chest wall. Occasionally the patient will walk farther than one would expect from the history; motivation and the inability of the patient to tolerate any respiratory discomfort may, in fact, be the cause of the patient's limitation. It is not uncommon for patients who lead extremely sedentary lives, especially if they have been told they have a condition that may cause shortness of breath, to interpret any increase in ventilation as pathologic.

LABORATORY ASSESSMENT

The laboratory is only occasionally of help in the diagnosis of dyspnea. Anemia of any cause may contribute to

dyspnea. Polycythemia may be the only clue to chronic hypoxemia. Elevation of the erythrocyte sedimentation rate may suggest occult infection or autoimmune disease. A chemistry panel may reveal occult renal disease or acid-base derangement; elevated serum bicarbonate level may be a clue to the presence of hypercapnia. More elaborate screening may uncover collagen vascular or thyroid disease. Measurement of B-type natriuretic peptide level is finding wide acceptance in refining the differential diagnosis of acute dyspnea,^{97,98} primarily in the emergency department setting,⁹⁹ where its use has been shown in a meta-analysis to reduce the duration of hospitalization but not to change other clinical outcomes.¹⁰⁰ The ventricle secretes B-type natriuretic peptide in response to elevated pressure. Therefore it is usually elevated in patients with left ventricular failure or cor pulmonale but not in patients with exacerbations of obstructive lung disease. It has been shown to be more accurate than echocardiography in recognizing left ventricular dysfunction as a cause of acute dyspnea.¹⁰¹

The clinical database should include chest radiography, spirometry, and possibly electrocardiography. Chest radiographs are useful when abnormal but are insensitive for detecting early obstructive and interstitial diseases; approximately 10% of patients with interstitial disease will have a normal chest radiograph. *Computed tomography pulmonary angiography* (CTPA) has become the standard modality for assessment of suspected thromboembolic disease. Although it is not recommended as a general screening test, it can be used to assess for both occult interstitial lung disease and thromboembolic disease in patients with evidence of gas-exchange abnormalities, for example, low diffusing capacity and/or hypoxemia at rest or with exercise (desaturation on exercise oximetry), or pulmonary hypertension on echocardiography.

Spirometry is a useful screening test for both airway and parenchymal disease. Because airway obstruction in asthma may be intermittent, monitoring peak flow at home or in the workplace may be productive. The yield of routine electrocardiography is low, although it may reveal previously unsuspected coronary artery disease, occult valvular disease, or diastolic dysfunction and can suggest pulmonary hypertension (i.e., if signs of right ventricular hypertrophy or tricuspid regurgitation are present). As ultrasound technology has advanced, small hand-held ultrasound machines are increasingly being employed by nonradiologists at the bedside, particularly to assess left ventricular function, central venous pressure, alveolar filling, and pleural effusion.^{102,103}

SPECIAL STUDIES (INCLUDING PULMONARY FUNCTION TESTS)

An array of special studies may be required for the diagnosis of conditions causing dyspnea (Table 29-3). Pulmonary function tests are useful but correlate only moderately with the severity of the dyspnea.¹⁰⁴ In the patient with episodic dyspnea but with normal spirometry results, methacholine inhalation testing can aid in the diagnosis of asthma. Patients who characterize their dyspnea as "chest tightness" are most likely to have positive study results.¹⁰⁵

Pulse oximetry may reveal previously unrecognized hypoxemia, a possible clue to many diseases. Because the

 Chest CT scanning (high-resolution)
 Chest CT pulmonary angiography
 Gallium scanning
 Diaphragmatic fluoroscopy

CARDIAC EVALUATION

Echocardiographic or radionuclide ventriculography
 Thallium scan
 Holter monitoring (for occult ischemia or arrhythmia)
 Cardiac catheterization (preferably with exercise for assessment of left atrial and pulmonary artery pressure)

ESOPHAGEAL EXAMINATION OR pH MONITORING**OTOLARYNGOLOGIC ASSESSMENT****SLEEP STUDIES****PSYCHOLOGICAL ASSESSMENT**

CT, computed tomography; DL_{CO} , diffusing capacity for carbon dioxide.

lungs have significant reserve capacity at rest, exercise oximetry may be necessary to elicit hypoxemia in patients with abnormalities of gas exchange. Oximetry should always be assessed in patients with a low diffusing capacity, which may be seen in individuals with emphysema, pulmonary vascular disease, and interstitial lung disease. Orthodeoxia (i.e., hypoxemia worse in the upright position) leads to a search for one of the many causes of this unusual condition.^{92,93,106}

If ventilatory muscle weakness is suggested by the patient's history, physical examination, or measurement of lung volumes, ventilatory muscle strength should be assessed. Maximal inspiratory and expiratory pressures can be measured easily and followed sequentially over time.

Cardiopulmonary exercise testing helps determine whether exercise is limited by the pulmonary, cardiovascular, or musculoskeletal system.⁶⁹ To the extent that patients with lung disease are frequently at risk for or have concurrent cardiac problems due to cigarette smoking, cardiopulmonary exercise testing can be very useful. Unfortunately, exercise testing is insensitive for distinguishing cardiac disease from deconditioning.¹⁰⁷ Therefore additional cardiac evaluation may be required. CTPA has replaced ventilation-perfusion lung scanning as the screening procedure of choice for the diagnosis of pulmonary embolic disease.^{108,109} One should remember that patients with chronic thromboembolic disease often present with gradually worsening dyspnea in the absence of episodic breathlessness characteristic of acute pulmonary embolism.

If exercise testing suggests cardiac dysfunction, echocardiography, radionuclide scanning, measurement of B-type natriuretic peptide, or even cardiac catheterization (preferably combined with supine exercise) may identify

unsuspected ventricular dysfunction, valvular disease, or pulmonary hypertension.^{101,110} Diastolic dysfunction, characterized by normal ventricular pressures at rest but elevations during exercise, is a common cause of heart failure but is frequently missed as the cause of exertional dyspnea. In a patient with a history of hypertension and/or left ventricular hypertrophy, diastolic dysfunction should be considered, even in the presence of normal systolic function on an echocardiogram. Stage III cardiopulmonary exercise testing (with pulmonary artery catheter in place) might be necessary to confirm the role of diastolic dysfunction in the patient's symptoms.

Gallium and high-resolution CT scanning are sensitive but not specific for occult infectious and inflammatory lung disease.¹¹¹

It is clear that a cascade of special studies might be necessary before reaching a specific diagnosis. If extensive testing is unrevealing, psychiatric evaluation may be valuable, especially if there is a strong emotional or behavioral component. However, it is more likely that the patient has an early stage of an as-yet-undiagnosed condition that may be revealed by serial testing.

SYMPTOMATIC TREATMENT OF DYSPNEA

Dyspnea can be most effectively alleviated by treatment of the underlying disease and its complications. The focus should be on alleviating symptoms as well as improving pulmonary function.^{112,113} Lung volume-reduction surgery for relief of dyspnea in advanced emphysema deserves special mention. Removal of multiple bullous or emphysematous portions of the lungs reduces hyperinflation and improves lung recoil, potentially leading to dramatic improvement in pulmonary function and dyspnea for some individuals.¹¹⁴ Because of the morbidity associated with surgical approaches to lung volume reduction, however, bronchoscopic approaches that employ endobronchial valves, coils, and biologic and polymer glues to block ventilation of bullous regions, thereby leading to volume reduction as air in the bullae is absorbed, are being studied.^{115,116}

When dyspnea persists despite optimal treatment of the underlying disease, treatment should focus on the symptom rather than the disease and particularly on the specific mechanisms contributing to an individual's dyspnea (e.g., respiratory muscle dysfunction, hypoxemia, anxiety).^{1,113} Until guidelines for specific therapy are established, one must take a generic approach to treatment, with a focus on improving respiratory muscle function, decreasing respiratory drive, altering the central nervous system experience of dyspnea, and instituting exercise training (Table 29-4 and Fig. 29-3).

REDUCING RESPIRATORY EFFORT AND IMPROVING RESPIRATORY MUSCLE FUNCTION

Energy conservation techniques reduce physical effort (e.g., by walking more slowly) and thereby reduce the necessary ventilatory effort. Breathing techniques (e.g., pursed lips) may reduce respiratory discomfort by slowing breathing,

Table 29-4 Symptomatic Treatment of Dyspnea**REDUCE SENSE OF EFFORT AND IMPROVE RESPIRATORY MUSCLE FUNCTION**

Energy conservation (e.g., pacing)
 Breathing strategies (e.g., pursed-lip breathing)
 Position (e.g., leaning forward)

USE EXERCISE TRAINING ALONE OR WITH PULMONARY REHABILITATION

Enhance self-esteem and self-confidence in ability to perform
 Improve efficiency of movement
 Improve oxygen delivery and utilization by skeletal muscles
 Desensitization to dyspnea (e.g., from repeated exercise)

Figure 29-3 The cumulative benefits of treatment on time of exercise endurance at a set workload and dyspnea as measured by a visual analogue scale. The endurance time gradually improves with cumulative treatment using a bronchodilator metered-dose inhaler (MDI), oxygen (O₂), and exercise training. Dyspnea relative to the workload is relieved both at rest and during exercise, even though maximum dyspnea remains about the same. Improvement on exercise testing should translate into improvement with activities of daily living so the patient should experience less dyspnea with activities of daily living.

reducing hyperinflation, and improving oxygen saturation.^{117,118} In a Cochrane systematic review, breathing exercises over 1 to 4 months were shown to improve functional capacity in patients with COPD¹¹⁹; effects on dyspnea, however, were inconsistent, perhaps due to the variable causes of dyspnea within this population. If ventilation limits exercise, strengthening the respiratory muscles should improve maximal ventilation and exercise performance, thereby alleviating the dyspnea. Unfortunately, the

results of this approach have been inconsistent,^{120,121} although one meta-analysis concluded that it can be of value especially in patients with documented respiratory muscle weakness.¹²² Efforts to reduce turbulent flow and the consequent work of breathing by having the patient inhale a mixture of helium and oxygen (i.e., heliox, low-density gas relative to oxygen alone, or oxygen plus nitrogen) have been effective in cases of upper airway narrowing,¹²³ but data in asthma¹²⁴ and COPD¹²⁵ have been mixed; exercise function may be improved in patients with COPD who exercise while inhaling heliox, but changes in dyspnea are inconsistent.¹²⁵

Nutritional repletion of cachectic patients can improve respiratory muscle strength and decrease dyspnea, although the clinical effectiveness of this therapy is unclear.^{120,126} It is intuitively appealing to “rest” chronically “fatigued” respiratory muscles with mechanically assisted ventilation (positive or negative pressure) so they perform better with less dyspnea; although not all studies have shown much benefit,¹²⁷ there is increasing evidence in support of this management strategy in patients with exacerbations of chronic diseases¹²⁸ or respiratory failure.¹²⁹ In less acute circumstances, a meta-analysis concluded that acute non-invasive ventilatory support during exercise does relieve dyspnea and improves exercise performance in COPD.⁴⁸ Studies of medications to relieve dyspnea by increasing muscle contractility have been unconvincing.¹³⁰

DECREASING RESPIRATORY DRIVE

Because many forms of dyspnea are closely related to the respiratory drive, treatments that reduce the drive should reduce dyspnea. Supplemental oxygen can reduce carotid body activation and decrease dyspnea by decreasing ventilation and reducing hyperinflation during exercise.¹³¹ Oxygen may also decrease dyspnea by improving ventilatory muscle function,¹³² enhancing left ventricular contractility, and reducing pulmonary artery pressure.¹³³ Supplemental oxygen administered via nasal cannula may reduce dyspnea in large part by stimulating flow receptors in the nasopharynx, which reduces the drive to breathe.¹³⁴ The amount of oxygen should be titrated to prevent desaturation below 90%, although even higher amounts may be advantageous for preventing dyspnea and improving exercise performance. Indeed, oxygen supplementation can improve exercise capacity in individuals without exercise hypoxemia.¹³⁵ Oxygen supplementation is recommended for use during pulmonary rehabilitation programs.¹²¹

Treatments aimed at peripheral receptors or reflex pathways have shown some positive results. In healthy subjects, topical anesthesia of airway receptors¹³⁶ or buccal mucosa¹³⁷ reduced experimentally induced breathlessness. Inhalation of furosemide, proposed to potentiate activity of slowly adapting stretch receptors in the lungs, has been shown to reduce dyspnea in some individuals with COPD.^{45,46} In studies in COPD patients, a fan blowing air on the face has been shown to decrease dyspnea,¹³⁸ and chest wall vibration¹³⁹ has been shown to reduce exertional dyspnea, raising hope for treatments directed at peripheral receptors. More drastic surgical approaches, including vagal nerve section and carotid body resection, have always been controversial and are not currently available.

ALTERING CENTRAL PERCEPTION

The experience of dyspnea is affected by many factors, including education, cultural background, knowledge, emotional state, bodily preoccupation, and prior experience. Some recent studies of dyspnea relief emphasize the importance of central processes in decreasing dyspnea.¹⁴⁰ Individuals with dyspnea that cannot be explained by cardiopulmonary disorders appear to be particularly sensitive to the unpleasantness of dyspnea associated with acute hypercapnia.¹⁴¹ Altering the central experience of dyspnea may be helpful even when physiologic approaches are inadequate.¹ Education, including specific coping strategies (e.g., muscle relaxation¹⁴²), helps patients understand their disease and develop feelings of mastery over it.¹⁴³ Sharing experiences with others or psychotherapy may reduce the intensity of the dyspnea and the distress associated with it.^{144,145} These educational and psychosocial strategies for symptom management have been comprehensively reviewed, and their use, in conjunction with exercise training, is recommended.¹²¹

Most discussions of centrally acting drugs for dyspnea focus on opiates. Opiates do have pharmacologic effects that should reduce the severity of the dyspnea (including reduction in ventilation), and it is likely that opiates can affect an individual's experience of dyspnea as they do for pain.^{146,147} However, fear of side effects, especially respiratory depression, has discouraged their use in patients with COPD.¹⁴⁸⁻¹⁵¹ Some of these fears may be unwarranted. In a study of normal individuals in whom dyspnea was induced in a laboratory environment, small doses of morphine relieved dyspnea with relatively minor effects on minute ventilation.¹⁵² Furthermore, in laboratory studies in COPD patients, opiates have produced modest improvement in exercise performance and dyspnea scores and only slight and infrequent side effects (e.g., drowsiness) with benefits that have been related both to decreases in ventilatory requirements for a given workload and to reductions in the perception of breathlessness at each level of ventilation.^{146,153} Conversely, placebo-controlled outpatient studies have shown inconsistent benefits and frequent side effects.^{148,150,154,155} For example, in a 14-week controlled crossover study of 16 patients with severe stable COPD,¹⁵⁴ long-acting morphine produced no relief of the dyspnea as measured by the Chronic Respiratory Disease Questionnaire or during walking. However, the authors emphasized that one subject had a "spectacular" response and continued treatment. Almost all of the subjects experienced significant, although not life-threatening, side effects. Thus opiates may be appropriate for dyspnea in an occasional carefully selected patient with far-advanced disease.¹⁵⁶

Opiates are less controversial for palliation of dyspnea in terminal malignant disease or chronic respiratory failure. Patients with severe COPD fear suffocating,¹⁵⁷ and, in this setting, the importance of relieving suffering despite the risk for shortening life is more widely accepted. Several systematic reviews clearly demonstrate the efficacy of this approach in the palliation of refractory dyspnea,^{158,159} and several major national professional societies include opiates for consideration in the palliation of dyspnea.¹⁶⁰⁻¹⁶²

Based on the concept that there are opiate receptors in the airways, inhalation of opiates has been examined as a

way of relieving dyspnea without the side effects seen with systemic administration. Despite earlier reports that inhaled opiates increased submaximal exercise endurance time in patients with severe COPD¹⁶³ and reduced dyspnea in patients with terminal lung disease and heart failure,¹⁶⁴ recent systematic reviews based on controlled trials have failed to demonstrate any real benefit of administering opiates by this route.^{158,159}

Centrally-acting pharmacologic agents have a limited role in the treatment of dyspnea, although controlled studies of unselected COPD patients have shown no benefit of anxiolytics on dyspnea.^{148,165} Similarly, there is little experimental evidence to support the use of antidepressants in the management of dyspnea, although positive results have been reported in case studies.^{166,167} Despite a lack of evidence, there is widespread recognition that there are clear clinical associations between dyspnea, anxiety, and depression. It is thought that individual patients with chronic dyspnea can benefit by targeting psychological morbidities with appropriate therapies.^{168,169}

ROLE OF EXERCISE TRAINING IN RELIEVING DYSPNEA (see Chapter 105)

There is now convincing evidence that pulmonary rehabilitation programs, along with improving exercise capacity and health-related quality of life, improve the symptom of dyspnea in patients with COPD.¹²¹ Exercise training appears to be a critical part of pulmonary rehabilitation programs for reduction of dyspnea, and, although one randomized, controlled study reported a better outcome with high-intensity compared with moderate-intensity training,¹⁷⁰ further studies are needed to clarify the impact of training intensity on dyspnea outcomes. Although most studies have employed endurance training using treadmills or cycles in supervised clinical environments, there is accumulating evidence that pulmonary rehabilitation programs can yield dyspnea-related benefits with (1) interval training,¹⁷¹ (2) strength training,¹⁷² and (3) home-based exercise training.¹⁷³ Individuals who report high levels of anxiety and fear related to dyspnea may be particularly responsive to the benefits of exercise programs.²³ It is not certain how important the educational component of pulmonary rehabilitation is in relieving dyspnea. A program of dyspnea management (including relaxation, breathing retraining, pacing, self-talk, and panic control) without an exercise component was compared with general health education; neither measure alleviated the dyspnea or improved the 6-minute walking distance.¹⁷⁴ By contrast, it has been shown that treadmill training with or without nurse coaching is equally effective in reducing dyspnea during exercise testing and activities of daily living.¹⁷⁵ Despite uncertainty about the impact of education per se on dyspnea outcomes, current recommendations strongly endorse the inclusion of an educational component as part of a pulmonary rehabilitation program.¹²¹

Exercise training may relieve dyspnea by many mechanisms. Neither pulmonary mechanics nor respiratory muscle strength is usually affected.^{121,176} True conditioning may decrease lactate production and decrease stimulation of ventilation even in patients with severe disease.¹⁷⁷ Relaxation and increased mechanical efficiency (e.g.,

longer stride length¹⁷⁸) may lower oxygen consumption and ventilation for a given activity.¹⁷⁹ Exercise training may improve self-confidence, thereby reducing anxiety and dyspnea.^{23,180,181} Repeated exercise may result in desensitization to the symptom (i.e., the same ventilatory stimulus results in less dyspnea^{57,175,182,183}). In any one patient, it is difficult to know which of these mechanisms is operant, but for clinical purposes, it may not matter.

RELIEF OF DYSPNEA IN END-STAGE LUNG DISEASE

Dyspnea is one of the most devastating symptoms known to human beings. In no area of medicine is relief more important than when dealing with dyspnea in end-stage lung disease. The severity of this symptom is well recognized in terminal malignancy, interfering with both physical and psychological function.¹⁸⁴ This awareness is lacking in other areas of terminal lung disease, where most information is anecdotal.^{185,185a} One exception is the treatment of the terminal phase of amyotrophic lateral sclerosis. The value of opiates and anxiolytics for relief of symptoms (especially dyspnea) in the last 24 hours of life of patients with amyotrophic lateral sclerosis has been documented by postmortem telephone interviews with family members in both the United Kingdom and Germany.¹⁸⁶

Although patients with chronic lung disease are normally encouraged to exercise to maintain their state of fitness, there comes a time when a different approach is required and the focus shifts from prolongation of life to relief of distress.^{160,161,185} When dyspnea with exertion is extreme, it may be more appropriate to restrict activity and to focus on treatments such as oxygen, opiates, and anxiolytics. Palliative treatment may include partial ventilatory support or, under rare circumstances, a tracheostomy with mechanical ventilation. Such dramatic steps to relieve dyspnea must be taken with full understanding of the ramifications and complications. As mentioned, many patients with end-stage COPD fear suffocation at the end of life.^{157,187} Some patients might choose a morphine drip to allow a comfortable death, whereas others might choose an aggressive approach focused on prolongation of life as well as relief of discomfort. It is up to the health care provider to help the individual patient understand these choices.

Key Points

- Dyspnea is a complex symptom arising from the central processing of information relayed from the respiratory complex, with modifying information from numerous afferent sources.
- The sensory information is integrated within the context of the psychological and intellectual makeup of the individual. It is still unclear whether there is a final common pathway for the sensation.
- Dyspnea is increasingly viewed as a multidimensional symptom, with qualitative and affective components in addition to sensation intensity components.
- Dyspnea may be due to diseases in virtually any organ system, whether caused by interference with breathing, increased demand for breathing, or weakening of the respiratory pump. In most cases, however, one is

dealing with a disorder of the respiratory or cardiovascular system.

- Diagnosis of the underlying condition causing dyspnea requires a comprehensive database. Cardiopulmonary exercise testing may be particularly useful when a patient has concomitant cardiopulmonary diseases or when cardiovascular deconditioning is suspected.
- When the cause of dyspnea is not obvious, a series of studies analyzing cardiopulmonary function at rest and with exercise usually uncovers a specific diagnosis. Sophisticated studies of the heart, pulmonary vascular bed, lung parenchyma, and even esophagus may be necessary.
- Treatment of dyspnea is most effective when it is based on a specific diagnosis. When treatment of the underlying disease is inadequate, treatment should focus on relieving the intensity and/or the unpleasantness of the symptom.
- A combination of education, exercise training, oxygen, and muscle strengthening aids most patients; in far-advanced disease, compassion may require the use of agents that directly blunt the often frightening and debilitating sense of breathing discomfort even though they may shorten life.

INTRODUCTION

Cough is a symptom that has been experienced by every human and is an essential innate protective mechanism that ensures the removal of mucus, noxious substances, and infections from the larynx, trachea, and large bronchi. Cough also minimizes the inhalation of toxic material. Impairment or absence of coughing can be harmful or even fatal in disease. Cough may also be a sign of disease in or outside the airways and lungs and a useful indicator for both patient and physician for initiating diagnosis and treatment of disease processes. When cough itself is persistent and excessive, it can be harmful and deleterious and may need to be suppressed directly.

Because cough is a normal defensive mechanism, it is a symptom experienced by healthy individuals. Epidemiologic surveys have shown that between 11% to 18% of the general population report a persistent cough,¹⁻³ but it is not known how much this cough is "normal" or is associated with disease. Reports of chronic cough in these surveys may be due to the presence of cigarette smokers; the exposure of an urbanized population to environmental indoor and outdoor irritants and air pollution; or undiagnosed illnesses associated with cough. The potential contribution of irritants to cough is illustrated by the report of excessive cough in New York firefighters who worked in the dust fallout of the World Trade Center attacks on September 11, 2001.⁴ Cough is also a common presenting symptom to the clinician. In the United States, cough is the most common complaint for which patients seek medical attention and the second most common reason for a general medical consultation; patients with persistent cough constitute about 10% to 38% of a chest specialist outpatient practice. In the United Kingdom, about 3 million prescriptions are written annually for cough preparations by general practitioners, representing a cost of \$3 million; this is an underestimate

because a vast number of cough mixtures are also bought over the counter without a medical prescription. In the United States, cough and cold medicines sold over the counter between 2007 and 2012 amounted to \$2.3 billion.

DEFINITION OF COUGH

Cough is initiated as a series of respiratory maneuvers that leads to a sudden expulsion of air creating a characteristic cough sound. It usually starts as a deep inspiration, followed by a strong expiration against a closed glottis, which then opens with an expulsive flow of air, followed by a restorative inspiration; these are the inspiratory, compressive, expulsive, and recovery phases of cough (Fig. 30-1). The cough sound in the first of three phases is an explosive sound heard during the expulsive phase consisting of a noiselike waveform. This is followed by an intermediate phase when there is decreased airflow associated with a decreasing sound amplitude. Finally, there is often a third phase called the *voiced* or *glottal* phase, that constitutes the second sound, produced by the vibration of a partly closed glottis, which produces a regular periodic noise (Fig. 30-2; listen to the associated Audios 30-1 and 30-2).

The initial inspiration of cough may be followed by a series of expiratory efforts, with closures of the glottis but not intervening inspirations—a "cough bout" or an "epoch" (see Fig. 30-2). Punctate mechanical stimulation of the trachea or larynx causes a brief but strong expiratory effort—the "expiration reflex"—rather than a true cough and, in the case of the glottis, reflex glottal closure⁵⁻⁷; these reflexes presumably act to prevent or minimize entry of foreign material into the trachea and lungs. Throat clearing, as in postnasal drip, consists more of this expiration reflex or "huff" than a full cough. Not only are there different patterns of "cough," but these patterns may be

Figure 30-1 Diagrammatic representation of the changes of the following variables during a representative cough: sound, flow rate, subglottic pressure. During inspiration, the flow rate is negative; at the glottic closure, the flow rate is zero; and during the expiratory phase, the flow rate is positive. The expiratory phase can be divided into three parts: during the *first* expulsive phase (1), there is an explosive cough sound, the first cough sound; during the *second* phase (2), as the expulsive airflow diminishes, the sound amplitude diminishes; and during the *third* phase (3), the vibration of a partly closed glottis produces a regular periodic sound, the second sound. Refer to [Figure 30-2](#) for a representation of the cough waveform. (From Bonica JJ: *Obstetric analgesia and anesthesia*. World Federation of Societies of Anaesthesiologists, Amsterdam, 1980.)

differently affected by pharmacologic and physiologic inputs.⁵⁻⁷ Cough sounds may have clear harmonic patterns,⁸ but the basis of these patterns has been little analyzed and their significance, if any, has not been established. *Induced cough* is usually preceded by an awareness of airway irritation and an “urge-to-cough,”⁹ involving activation of sensory processing and limbic regions in the cerebral cortex.^{10,11} *Evoked cough* may be either involuntary (reflexively evoked) or voluntary (a behavioral outcome in response to the urge-to-cough), the former mediated by sensory inputs at a brain-stem level and the latter originating in motor regions of the cerebral cortex.^{12,13} It is unclear what proportion of cough in disease is reflexive versus behavioral. *Habit cough* is a variant of voluntary cough, which may or may not be associated with an urge-to-cough. Once a cough has been induced, there will be secondary feedbacks from both the lungs and the higher parts of the brain, which do not seem to have been analyzed.

Thus, the definition of cough may need to be extended to embrace, or at least consider, these different patterns and neural circuits. This consideration is not a semantic quibble. The various defensive respiratory patterns defined as cough have different afferent and central nervous pathways, but clinical descriptions of cough have seldom differentiated between them. Antitussive drugs could have selective

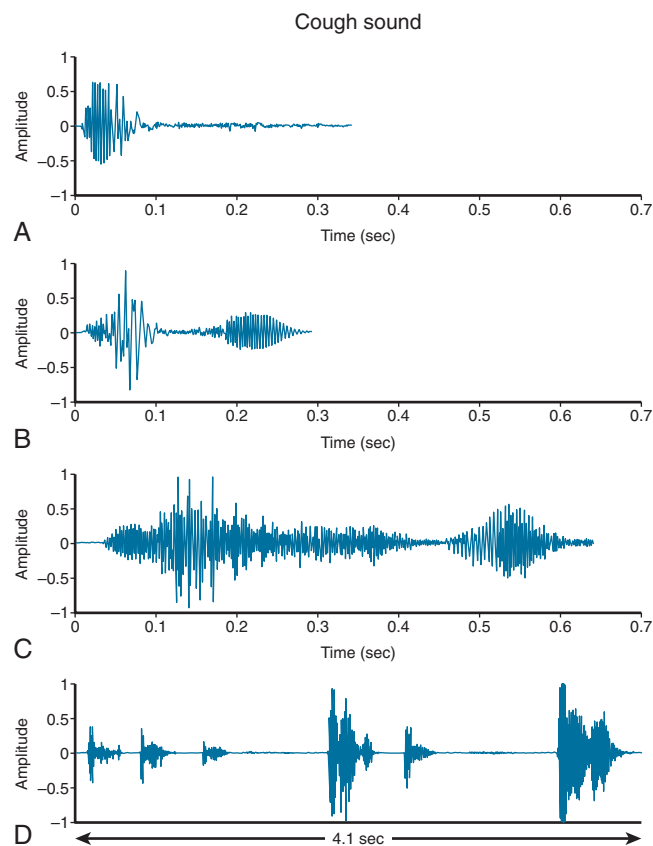

Figure 30-2 Cough sound waveforms from patients with a chronic cough. **Panel A** shows two phases with an initial expulsive phase that is the first cough sound, followed by an intermediate phase with decreasing sound. **Panel B** (from an “idiopathic” chronic cough) and **C** (from a patient with pulmonary tuberculosis) show an additional third phase called *voiced* or *glottal phase*, which gives rise to a second cough sound (refer to [Audio 30-1](#)). **Panel D** shows an epoch of six coughs in succession in a female subject with chronic idiopathic cough (refer to [Audio 30-2](#)). actions on the different neural pathways and therefore have different indications in the clinic.

PHYSIOLOGY

Experimentally, involuntary coughing appears to be initiated only from those structures innervated by the vagus nerve and its branches.^{5,14} These are predominately the larynx and the proximal tracheobronchial tree, but they also include the lower part of the oropharynx and the smaller bronchi, as well as the tympanic membrane and the external auditory meatus. Irritation of all these sites can cause coughing. The one clear exception to vagally mediated coughing is that caused voluntarily^{15,16} ([Fig. 30-3](#)); of all the highly complex defense mechanisms, cough is the only one that we can mimic voluntarily and accurately. We can also inhibit it voluntarily. Most patients can suppress their cough for 5 to 20 minutes if they try hard.¹⁵

Spontaneous coughing can be initiated by a wide variety of inflammatory or mechanical changes in the airways and by inhalation of a large number of chemical and mechanical irritants. Rapid and large changes in lung volume can

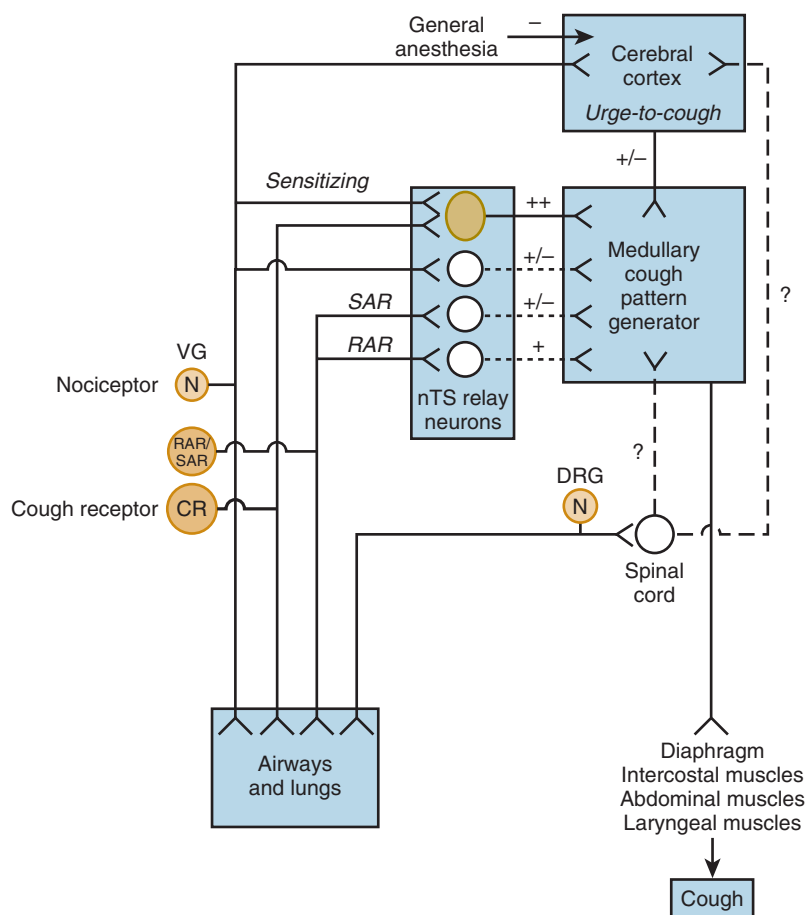

Figure 30-3 Model illustrating the afferent and efferent pathways in the control of cough. Rapidly adapting receptors (RARs), slow-adapting receptors (SARs), and nociceptors (N) may modulate the cough responses, and a distinct set of cough receptors (CR) has been described in the guinea pig. There may be promotion of coughing through interactions with cortical and brain-stem structures, in addition to putative contributions via spinal airway afferents. The cough pattern generator coordinates the output to muscles and effectors that results in the cough response. However, voluntary cough pathways arising from the cortex may bypass the brain-stem respiratory centers and directly regulate spinal respiratory motor neurons (not shown). DRG, dorsal root ganglion; nTS, nucleus tractus solitarius; +, enhancing; -, inhibitory; ?, putative, +/-, evidence for both enhancing and inhibiting exists. (Adapted and updated from Mazzone SB: Sensory regulation of the cough reflex. *Pulm Pharmacol Ther* 17:361–368, 2004.)

cause cough, as can psychological effects such as laughter. The extremely wide variety of stimuli that can trigger cough points to a similarly wide range of properties of the sensory receptors that are the starting point of the cough reflex.^{5,14,17}

SENSORY RECEPTORS FOR THE COUGH REFLEX

The most sensitive sites for initiating cough are the larynx and tracheobronchial tree, especially the carina and points of bronchial branching.^{5,14,17–19} Inhaled materials impinge on these points. In experimental animals and humans, it is difficult or impossible to induce coughing from the smaller airways and alveoli. This is teleologically understandable because in the smaller airways even a vigorous cough would not move gas fast enough to cause turbulence and shearing forces at the airway wall, so the cough would be ineffective. In view of the wide range of stimuli for coughing, one would expect that there would be several types of cough-evoking sensory nerves and that the sensory nerve receptors would be “polymodal” (i.e., to respond to a variety of chemical, physical, and pharmacologic mediators). Indeed, at least two types of airway sensory nerve subtypes for initiating cough have been described and these each respond to a range of different stimuli.²⁰ However, broadly speaking these sensory subtypes can be categorized as either nociceptors, which detect a range of noxious chemical irritants but are relatively insensitive to mechanical stimuli, or mechanoreceptors, which have some (but

limited) chemosensory properties but are exquisitely sensitive to punctate (touchlike) mechanical stimuli.

Larynx and Pharynx

Nerve receptors (or perhaps better termed “sensors,” which is used in this chapter) in the laryngeal mucosa are activated by the mechanical and chemical stimuli for cough; their fibers run mainly in the superior and recurrent laryngeal nerves before joining the vagus nerves. Many studies of laryngeal afferent innervation suggest that the sensors for cough belong to the broad group of *rapidly adapting receptors* (RARs), albeit a different class to the classic RARs described in the intrapulmonary airways and lungs.^{21–24} Laryngeal and pharyngeal mechanosensors are normally silent, as would be expected and, when activated, cause rapidly adapting discharges with an irregular pattern that are conducted in fast-velocity vagal myelinated (A δ) fibers. Their many stimuli include cigarette smoke, ammonia, ether vapor, acid and alkaline solutions, hypotonic and hypertonic saline, and punctate mechanical stimulation by catheter, mucus, or dust (but not stretch or bronchospasm); all these stimuli can provoke cough. The larynx and pharynx are also innervated by cough-evoking nociceptors. These are unmyelinated slow conducting C-fibers that are characterized by their responsiveness to the chemical capsaicin, the active ingredient in hot chili peppers. Nociceptors are also responsive to a wide range of proinflammatory molecules, which notably include bradykinin, prostaglandins,

ASIC, acid-sensing ion channel; TRPA1, transient receptor potential cation channel, subfamily A, member 1; TRPV1, transient receptor potential vanilloid-1 receptor. (Redrawn and modified from Undem BJ, Carr MJ, Kollarik M: Physiology and plasticity of putative cough fibers in the guinea pig. *Pulm Pharmacol Ther* 15:193–198, 2002.)

leukotrienes, proteases, and cytokines, as well as noxious irritants such as capsaicin, acid, nicotine, and acrolein.²⁵ Laryngeal nociceptor activation during anesthesia has been shown to induce apnea rather than cough, which might indicate that these sensory fibers are inhibitory to cough. However, studies in conscious animals show laryngeal nociceptor activation to be a powerful stimulus for coughing, suggesting that anesthesia confounds the role of laryngeal nociceptors in generating cough responses.

Although strong cough can be induced from the larynx, its denervation or bypass makes little difference to the strength of cough caused by inhaled irritants. As with many protective/defensive mechanisms, the cough reflex displays much “redundancy”—that is, a doubled sensory input for cough does not result in a doubling of the motor response. Activation of sensors in the larynx or pharynx may cause either a “typical” cough, starting with an inspiration, or the expiration reflex, starting with an expiratory effort.^{5–7} The difference is presumably due to various types of cough sensors in the mucosa or the timing of the sensory input to the brain stem relevant to the respiratory cycle. Although cough induced from the pharynx may seem to be the exception to the vagal rule, in that the pharynx is supplied mainly by the glossopharyngeal nerve, there is a small pharyngeal branch of the superior laryngeal (vagal) nerve that could mediate cough, and this seems to be especially active in humans.²⁶ For example, postnasal drip associated with inflammation due to nasopharyngitis and sinusitis can

induce cough possibly due to spread of inflammatory mediators into the larynx.

Tracheobronchial Tree

Touch-sensitive (stretch-insensitive) mechanosensors are also found in the trachea and large bronchi of those species that cough. These sensors have nerve terminals under or within the epithelium (Fig. 30-4), concentrated at points of airway branching; some of them lie close (1 μm) to the epithelium.^{27–29} Their appearance and location suggest that they might be sensitive to intraluminal irritants or particulate matter that physically displaces the epithelium. They are comparable with those in the larynx in their sensitivity to chemical and mechanical irritants. Farther along the bronchial tree in the intrapulmonary airways and lungs, the mechanoreceptors change functionally in that they gain sensitivity to stretch stimuli, as well as additional chemosensitivity (notably becoming sensitive *adenosine triphosphate* (ATP) analogues that activate purinergic receptors).²¹ These sensors represent the classic RARs known to be involved in the Hering-Breuer deflation reflex. In experimental animals, intrapulmonary RAR activity is enhanced by pulmonary congestion, atelectasis, bronchoconstriction, and decreases in lung compliance, all of which can contribute to cough in patients. However, whether intrapulmonary RARs can directly initiate coughing is unclear. The other type of intrapulmonary mechanoreceptor (*slowly adapting stretch receptors* [SARs] involved in the

Hering Breuer inflation reflex) may inhibit cough through central mechanisms.

C-fiber sensors are also found in the tracheal, bronchial, and alveolar walls. They are activated by much the same range of stimuli as are those in the larynx, but their evoked responses are not homogeneous and, at least for those in the alveolar walls, do not include cough.^{17,29,30} In some species the C-fiber sensors may release tachykinins, such as substance P, by an axon reflex, which in turn causes neurogenic inflammation. This may explain the effect of tachykinin antagonists in inhibiting cough, although axon reflexes do not appear to be prevalent in human airways. C fibers are also responsible for generating the urge-to-cough, which may trigger behavioral coughing in an attempt to relieve the urge.³¹ Indeed, there is no convincing evidence that C-fiber receptors can be a primary sensory input for reflexive cough. Airway C-fiber sensors have been differentiated into two groups^{28,32} and, in the guinea pig, a new group of A δ -nociceptors has been identified. Jugular ganglia C fibers can initiate coughing, whereas nodose ganglia C fibers do not and may even be inhibitory to cough.^{33,38} The role of A δ -nociceptors in cough has not been defined. Thus, the fact that multiple sensory nerve subtypes can elicit or modify cough suggests that the total pattern of cough may be due to the interaction of several reflexes. This view, together with the variety of physiologic patterns of sensitivities and responses of mechanosensors and nociceptors in various parts of the respiratory tract, could explain the great divergence of cough patterns in different conditions and in different patients. The effectiveness of antitussive drugs that act at peripheral sites (e.g., by the inhalation of anesthetic aerosols) may depend on their relative actions on the different groups of receptors that affect cough or on their central connections.

Membrane Receptors/Channels on Sensory Endings for Cough

The past decade has seen extensive studies on the membrane/channel receptors in sensory nerves involved in coughing.^{29,34-37} The details are complex, so they are summarized only briefly; however, the results are of considerable importance in not only indicating how coughing may be induced but also by pointing to possible future targets in antitussive therapy.

Mechanically-activated cough sensors are stimulated by touch but not stretch and are thought to express mechanically gated membrane channels that are unique to this class of airway sensory neuron.²¹ These channels have yet to be identified. In addition, they have other channels that can be activated by acid and belong to the *acid-sensing ion channel* (ASIC) family and the NaV1.7 subtype of voltage gated sodium channels,³⁸ characterized by their sensitivity to the neurotoxin, tetrodotoxin. However, the mechanosensor membranes normally lack several *transient receptor potential* (TRP) channels, which are found in C- and A δ -nociceptors, namely the temperature-sensitive *transient receptor potential vanilloid-1* (TRPV1) and *transient receptor potential cation channel, subfamily A, member 1* (TRPA1) receptors, although the expression of these TRP channels on mechanosensors may be induced during inflammation.³⁹ TRPV1 receptors are directly activated by capsaicin, much used as a tussive agent, and are sensitized or indirectly activated by heat,

protons, bradykinin, arachidonic acid derivatives, ATP, and phosphokinase C. TRPA1 is coexpressed with TRPV1 on many vagal C fibers in the airways⁴⁰ and is activated by allyl isothiocyanate (mustard oil), cinnamaldehyde (from cinnamon), and acrolein (from cigarette smoke). TRPA1 has been shown to mediate a myriad of sensory nerve dependent processes and may interact functionally with TRPV1. C fibers also express tetrodotoxin-insensitive voltage-gated sodium channels.⁴¹

Thus, the way in which a large variety of tussive stimulants activate the sensory nerves responsible for cough and the urge-to-cough is beginning to be clarified, and it is now recognized that stimuli must produce the correct pattern of action potential firing in order to encode for coughing.⁴² Of note, the membrane receptors on cough sensors have been studied mainly in experimental animals,^{25,34} and their relevance to human cough is still unclear.

CENTRAL NERVOUS SYSTEM CONTROL

A (possible) circuit diagram for the interaction of cough inputs and outputs and the respiratory rhythm generator in the brain stem has been proposed.⁴⁴⁻⁴⁷ Reflex coughing is integrated in the medulla oblongata, where the afferent fibers for coughing first relay in or near the nucleus of the tractus solitarius; the motor outputs are in the nucleus retroambigualis, sending motoneurons to the respiratory muscles, and in the nucleus ambiguus, sending motoneurons to the larynx and bronchial tree. In the cat, brain-stem pathways for the expiration reflex differ from those for a typical cough,^{47,48} and pathways for cough from the larynx differ from those from the tracheobronchial tree.⁴⁹ These observations, if true for humans, may point to different antitussive agents appropriate to the two sites.

Afferent inputs to the brain stem are relayed to higher brain regions where inputs are integrated in pontine, subcortical, and cortical nuclei.³¹ However, these ascending pathways may be different for sensors innervating the upper versus lower airways.^{49a} Studies with functional magnetic resonance imaging of the human brain during induced cough are delineating those areas involved and have shown them to be important for the different sensory discriminative and motor aspects of noxious airway stimulation^{10-12,49b} (Fig. 30-5). For example, the anterior insula cortex is activated in a stimulus-dependent manner, suggesting that it plays a role in monitoring the amount of sensory input arising from the airways. The primary sensory cortex, on the other hand, is activated in a perception-dependent manner, suggesting that it is intimately involved in assimilating sensory inputs and coding for the urge-to-cough intensity. The posterior parietal and prefrontal cortices provide spatial awareness (i.e., where is the stimulus located), and parts of the limbic system (e.g., the orbitofrontal cortex) help shape emotive responses to the irritation. Cough can also be initiated voluntarily, a process that originates in motor and premotor cortical brain regions. These voluntary descending pathways can probably bypass brain-stem integrative centers^{15,16} (see Fig. 30-4) because some patients with brain-stem damage lack a spontaneous cough reflex but can consciously induce coughing to clear the airways.⁵⁰ The motor cortex and inferior frontal gyrus

Figure 30-5 Activation of brain pathways associated with inhalation of capsaicin to cause an “urge-to-cough” shown by functional magnetic resonance imaging in normal subjects. The images show activity combined from the different subjects at different levels of the brain. The majority of regional activations were distributed in both hemispheres, including the orbitofrontal cortex (A), inferior frontal gyrus (A and B), anterior insula (B and C), superior temporal gyrus (C), and primary motor and somatosensory cortices (D and G). Midline capsaicin activations include the supplementary motor area (E) and the anterior midcingulate cortex (F). The locations of capsaicin activations in the primary motor and somatosensory cortices were at the caudal end of the central sulci in both hemispheres (D) and are clearly discernible on the three-dimensional rendering of the left hemisphere. (A–G, From Mazzone SB, McLennan L, McGovern AE, et al: Representation of capsaicin-evoked urge-to-cough in the human brain using functional magnetic resonance imaging. *Am J Respir Crit Care Med* 176:327–332, 2007.)

can also generate cough suppression, which inhibits brain stem–mediated cough via poorly defined pathways.^{13,50a} Greater understanding of the central control of coughing is desirable because most antitussive drugs act centrally, and we know little about how they do this. However, research has shown that central nervous membrane receptors for cough include those that respond to serotonin, gamma-aminobutyric acid, *N*-methyl-*D*-aspartate (NMDA), neurokinins, and dopamine, results that could have considerable therapeutic implications.^{44,51}

The central nervous pathways for cough show interactions and plasticity, as do the peripheral mechanisms already described.^{52–54} For example, afferent fibers from mechanosensors and C-fiber receptors converge in the nucleus of the solitary tract. Neurokinins released from the latter potentiate the activity of the former, especially cough and reflex bronchoconstriction, and this potentiation is enhanced by continued C-fiber activity. Ongoing activity of peripheral afferents may therefore lead to central plasticity of cough circuits,⁵⁵ thereby reducing the need for peripheral inputs to elicit coughing. This is likely important for chronic cough in respiratory disease but may also be seen in some cases of *gastroesophageal reflux disease* (GERD), where activity in esophageal afferents, which do not normally cause cough, may activate the cough reflex when sensitization takes place.

MOTOR OUTPUTS

Although glottic closure is usually regarded as an essential and definitive component of cough, in both human and experimental animals, the closure may be incomplete or even absent, and this does not seem to impair the effectiveness of the cough in terms of airway clearance. In addition,

the glottal closure reflex has a lower threshold to irritants than does the expiration and cough reflexes and may therefore depend on different pathways.^{18,19}

Coughing is associated with respiratory actions other than those of the respiratory skeletal muscles.^{5,14,17} There is usually bronchoconstriction, although this may be masked or reversed by the dramatic changes in lung volume. The afferent mechanisms for reflex cough and reflex bronchoconstriction may be different, even though the initial stimulus is the same. Thus, extrapulmonary mechanosensors and jugular ganglia–derived C fibers may evoke cough, whereas the bronchoconstriction is mainly by intrapulmonary RARs and nodose ganglia–derived C-fiber sensors. Bronchoconstriction would increase linear velocity of airflow and lessen the inflow of irritant material to deeper parts of the airways.

The afferent sensors for cough also cause reflex secretion of mucus from airway submucosal glands.^{5,14,17,56} Mucus entraps inhaled particles and irritant chemicals, and the material is thus cleared from the airways by mucociliary transport and by the cough itself. Mucus could also act as a physicochemical barrier between the luminal irritants and the airway wall. However, an increase in mucus secretion in conditions associated with cough has never been accurately measured, perhaps because of lack of appropriate methods.

MECHANICS OF COUGHING

The inspiratory phase of cough consists of a deep inspiration through a widely opened glottis. The inhaled volume varies greatly, from a low to a nearly complete vital capacity. The inspiration may draw material into the lungs; however, the large lung volume provides a better mechanical

efficiency for the expiratory muscles of cough because they are stretched, their stretch reflex is activated, and there is a stronger elastic recoil of the lung to aid expiration. Furthermore, the deep inspiration opens the airways in preparation for their clearance during the expiratory phase.⁵³

In the compressive phase of cough, which lasts about 200 ms, the glottis closes while the expiratory muscles contract, and the intrapleural and intra-alveolar pressures rise rapidly to a range of values that can vary from 40 to 400 cm H₂O, which can be used as an index of the intensity of the cough.^{53,57} The expulsive phase follows when the glottis opens. The expiratory flow rate depends on both air leaving the central airways during dynamic collapse as a result of the high intrathoracic pressure and the effect of high alveolar pressure, increased during the compressive phase and maintained at a high level by the contraction of the expiratory muscles. The expulsive phase of coughing may be long-lasting, with a large expiratory tidal volume, or it may be interrupted by glottic closures into a series of short expiratory efforts, each having a compressive and an expulsive phase. What determines the pattern of coughing has not been established but may depend on the anatomic site of origin of the cough, on the different nerve types of receptor activated, and on the strength of their activation.

Maximum expiratory flow is effort independent because it is limited by dynamic compression of the airways.⁵³ This compression starts immediately downstream from the “equal pressure point” at which intraluminal and extraluminal pressures around the bronchial wall are equal so that transbronchial pressure is zero. The effectiveness of cough depends on peak airflow and will therefore be greater with a larger elastic recoil of the lung and a greater stiffness of the central airways. Dynamic compression of the airways downstream from the equal pressure point increases velocity, kinetic energy, and turbulence of the air passing through the proximal airways. Thus, the clearing capacity of the cough is improved. If cough consists of a series of expiratory efforts, with lung volume decreasing with each effort, dynamic compression is predicted to move into the more peripheral bronchi, which will be progressively cleared of intraluminal material. However, at present this description is largely theoretical and needs to be established experimentally.

Whereas mucociliary transport is the major method of clearing the airway lumen in healthy subjects, cough is an important reserve mechanism, especially in patients with lung disease. In many lung diseases, mucociliary clearance is impeded and cough is necessary to remove the increased amount of secretions and debris. Healthy subjects have twice the mucociliary clearance rate of that in patients with chronic bronchitis, but when cough is permitted or encouraged, the patients increase their clearance by 20%, whereas healthy subjects increase their clearance by only 2.5%. As would be expected, all studies point to the fact that cough is effective in causing clearance if there is hypersecretion of mucus; by definition, a dry cough is an unproductive one.

NEURAL MECHANISMS OF COUGH HYPERSENSITIVITY

In disease, the sensory receptors for cough can show an exaggerated response to stimuli that would normally be

harmless or mildly irritating. This increase in sensitivity of mechanosensors and C-fiber receptors can be caused by stimuli including allergen challenge, viral infections, ozone, cigarette smoke, and a variety of inflammatory mediators.³⁴ Mechanosensors can also be sensitized by mucus in the airways, smooth muscle contraction, and mucosal edema.^{29,30,35,52,58} Increases in sensitivity have been related to structural changes in the nervous receptors, in particular in their intracellular mediators, and in the nerve cell bodies in the jugular and nodose ganglia and in the afferent pathways entering the brain stem. These effects lead to central sensitization, a neural mechanism in the *central nervous system* (CNS) that amplifies incoming sensory inputs and produces hyperreflexic states.⁵⁹

The alterations in the structure and function of vagal sensory neurons and central processing pathways seen in disease models of *hypertussia* (increased cough sensitivity to known stimuli) reflect cough neuropathy (Fig. 30-6). The concept of a vagal sensory neuropathy producing airway hypersensitivity is comparable with the well-known role of peripheral sensory neuropathy leading to chronic pain syndromes.⁵⁵ In patients with neuropathic pain, damage or disease of the peripheral sensory nervous system or its central projection pathways underpins pain hypersensitivity, characterized by the clinical pain symptoms of hyperalgesia (an elevated sensitivity to painful stimuli) and allodynia (pain in response to nonpainful stimuli). Neuropathic pain may act in tandem with inflammatory pain mechanisms in which altered nerve fiber activity is associated with both local tissue inflammation, as well as damage or disease of the nervous system.^{60,61} Indeed, a host of inflammatory mediators released from resident and infiltrating cells can sensitize or damage the airway nervous system to alter its normal functions.^{25,41,62} Although the nerve damage in neuropathic pain may be easy to recognize (e.g., the crushing or severing of peripheral nerves associated with major trauma), neuropathies can manifest as a result of less apparent insults including viral infection, metabolic diseases (e.g., diabetes), and other causes of neuroinflammation.

APPROACH TO THE PATIENT WITH COUGH

As emphasized in all national guidelines,^{63,64} the approach to the management of a patient with cough is first to identify the cause(s) of the cough and then to treat the cause(s). Cough may be indicative of trivial or serious airway or lung diseases and also of extrapulmonary processes. Often, the cause may not be found, the treatment of the putative cause may not suppress or improve the cough, or the cause may have no effective treatment. In those cases, therapy that suppresses cough by inhibiting the cough pathway without treating the cause (“symptomatic,” “nonspecific,” or “indirect” antitussives) is necessary.

The differential diagnosis of cough is extensive and includes infections, inflammatory and neoplastic conditions, and many pulmonary, as well as extrapulmonary, conditions (Table 30-1). The protocol for investigating a chronic cough—defined as a cough that has persisted for

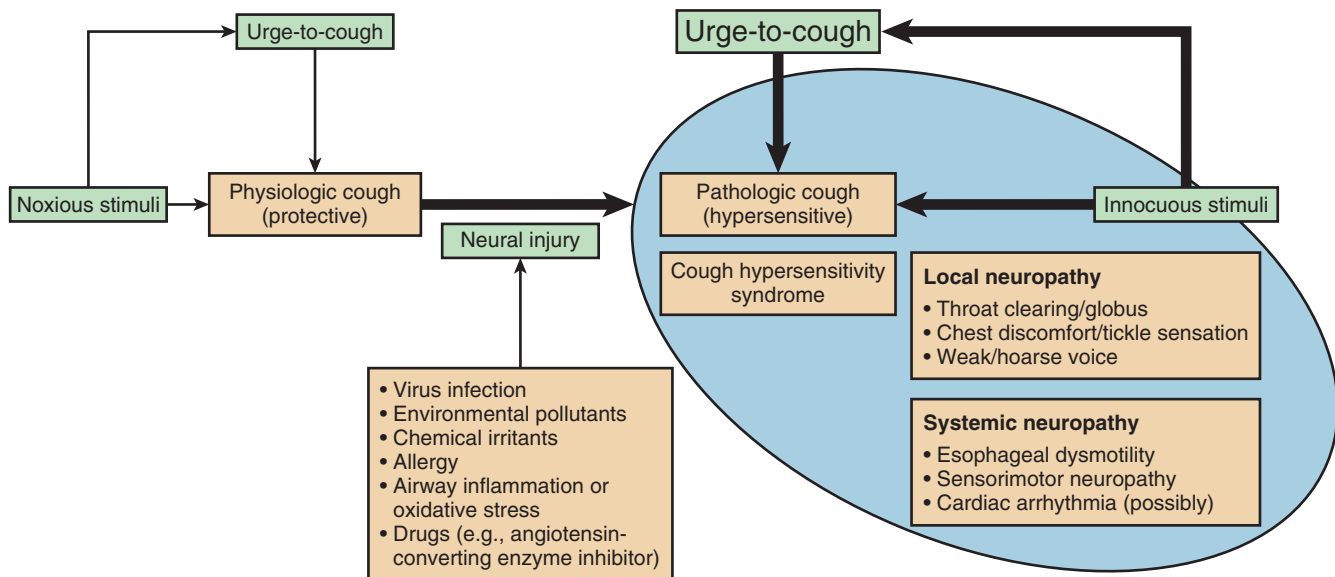

Figure 30-6 Cough hypersensitivity syndrome. The proposed effect of vagal nerve injury arises from inflammation caused by airway exposure to infective, physical, chemical, and allergic insults. The blue oval emphasizes the pathology (neuropathy) of the cough hypersensitivity syndrome. (From Chung KF, McGarvey L, Mazzone S: Chronic cough as a neuropathic disorder. *Lancet Respir Med* 1:414–422.)

more than 3 weeks—takes into account several factors pertaining to the pathophysiology of cough and to the most common causes of cough. Persistent cough may be due to the presence of excessive secretions, airway damage and infection, or the establishment of a hypersensitive cough reflex. A protocol based on systematic evaluation using history, examination, and laboratory investigations focusing on the anatomic sites of cough receptors that constitute the afferent limb of the cough reflex is a most widely advocated approach to diagnosis and treatment.

The foremost consideration for the clinician at the first visit is to (1) determine the severity, (2) assess the cause(s)

of the cough, and (3) plan investigations and treatment. Various indicators in the history and examination of the patient may provide clues to the diagnosis, although these may not be entirely reliable or specific and may be absent in many cases.

An acute cough due to an upper respiratory virus infection generally lasts for no more than 3 weeks, although some postviral coughs may persist for many weeks or months. Thus, a chronic cough is considered to be one that persists longer than 3 weeks. The one caveat is that many patients with an “idiopathic” cough often state that their cough originated during an upper respiratory tract infection. Nonetheless, a cough that has lasted for more than 2 to 3 months is unlikely to be due to an upper respiratory tract infection, and other associated causes must be investigated.

Cough with sputum production usually points toward conditions such as chronic bronchitis and bronchiectasis or other causes of bronchorrhea. The diagnostic value of knowing that the cough is productive is probably limited because similar causes are often found for both productive and dry cough.⁶⁵ In addition, the volume of sputum produced is difficult to estimate accurately (usually depending on sputum cups and block of salivary contamination), and coughing itself leads to sputum production. The concept of a dry versus a productive cough as delineating a cough secondary to an increased cough reflex for the former and a cough secondary to excessive mucus production for the latter is not entirely correct. An enhanced cough reflex may be present in both productive and nonproductive cough. Features that are associated with an increased cough reflex include cough triggered by taking a deep breath, laughing, inhaling cold air, and prolonged talking. Therefore, the diagnostic approach remains similar whether or not the cough is productive.

The characteristics of the cough, however, may sometimes help direct the diagnostic evaluation. Throat clearing

may be associated with a postnasal drip, a predominantly nocturnal cough may be attributed to asthma, or coughing after meals may be related to coexistent GERD. However, the predictive value of these characteristics is low.⁶⁶ A cough with a “honking” or “barking” quality, particularly in a child, has been associated with a psychogenic or habit cough.

Many cigarette smokers have a chronic cough but rarely seek medical advice regarding their cough because they expect that the irritant effect of cigarette smoke is the cause of their cough. However, chronic smokers may actually have a reduction in their cough reflex sensitivity, perhaps due to desensitization or damage of the epithelial nerve endings. A change in the pattern or characteristics of their cough, such as an increase in intensity (usually after an upper respiratory tract infection), or accompanying hemoptysis may force a smoker to seek medical attention. A chest radiograph is mandatory in this situation.

MEASURING COUGH

Assessment of cough frequency and severity rests mainly on the history. In very severe cough, patients may experience complications such as vomiting, rib fractures, tiredness, incontinence, and syncope (Table 30-2), and their presence indicates that the chronicity and intensity of the cough are severe. The effect of cough on the patient's lifestyle and psychological well-being may also provide an idea of the severity of the cough. Questionnaires that are specifically devised to measure these effects have been developed and validated.^{67,68} Direct measurement of the frequency and severity of cough has also been developed.^{8,69} In many published studies, the effectiveness of particular interventions on cough has been determined qualitatively in the clinic, but the use of more quantitative tools is now gradually being introduced (see later).

Cough can be measured in several ways: (1) cough severity can be judged by the patient recording her or his perception on a visual analogue scale ranging from mild to severe or on a nominal line from 0 to 10; (2) the cough reflex can be measured by counting the cough responses to inhalation of tussive agents such as capsaicin, the pungent extract of

peppers, or citric acid— or low-chloride-content solutions; (3) cough frequency and intensity can be measured by quantitative ambulatory recording; and (4) cough-specific, health-related quality of life questionnaires can provide a quantitative measure of the impact of chronic cough on the patient.^{67,68,70} There is a correlation between the various measures of cough as, for example, between objectively measured cough frequency and subjective scoring systems measured by the cough visual analogue scale or the Leicester Cough questionnaire, although this correlation remains weak.⁷¹ This means that subjective scoring systems may be responsive to not only cough frequency but also other factors related to the cough. Therefore, a combination of both subjective and objective measurements should ideally be used. All these features are of concern to the patient.

MEASUREMENT OF THE COUGH REFLEX

Persistent cough may result from an increase in the sensitivity of the cough sensors. Most patients with a persistent cough, due to a range of causes, have an enhanced cough reflex to inhalation of an aerosol of capsaicin or of citric acid when compared with healthy noncoughing subjects.⁷² Successful treatment of the primary condition underlying the chronic cough (specific or disease-specific treatment) sometimes leads to a normalization of the cough reflex.⁷³ The degree of the cough responsiveness to inhaled capsaicin may contribute to the severity of the cough. Of relevance to the evaluation and treatment strategies for persistent dry cough is the fact that the cough response can be augmented by various mediators of inflammation such as the *prostaglandins* PGE₂ and PGF_{2α} and bradykinin through a process of sensitization.^{74,75} Measurement of the cough reflex response to such agents may be useful in confirming the presence of a persistent cough or in assessing the response to treatment. At the moment, only centers with an interest in cough use it for clinical and research purposes.

MEASUREMENT OF COUGH FREQUENCY AND INTENSITY

Advances in computer technology and digital sound recording have led to the development of ambulatory systems for audio or audiovisual recording of cough, with the ultimate objective of automatically obtaining cough counts and possibly intensity in a real-life setting. Several devices have been described.^{8,76} The number of cough sounds and the cough seconds, a measurement of the time of coughing, have been shown to correlate with scores on a *Leicester Cough Questionnaire* (LCQ) and on a cough visual analogue scale.⁸

Although the methods are valuable in counting the number of expiratory efforts associated with cough, they do not allow assessment of cough intensity (because this need not correlate with intensity of expiratory sound). They can be used to differentiate between individual coughs and those associated with a cough epoch, although the definition of the distinction is arbitrary. Both the frequency and intensity of cough efforts are features of importance to the patient. Current methods do not allow a distinction between a “true” cough and an expiration reflex, a feature

Table 30-2 Potential Complications from Excessive Cough

RESPIRATORY	MUSCULOSKELETAL
Pneumothorax	Intercostal muscle pain
Subcutaneous emphysema	Rupture of rectus abdominis muscle
Pneumomediastinum	Increase in serum creatine phosphokinase
Pneumoperitoneum	Cervical disc prolapse
Laryngeal damage	
CARDIOVASCULAR	GASTROINTESTINAL
Cardiac dysrhythmias	Esophageal perforation
Loss of consciousness	
Subconjunctival hemorrhage	
CENTRAL NERVOUS SYSTEM	OTHER
Syncope	Social embarrassment
Headaches	Depression
Cerebral air embolism	Urinary incontinence
	Disruption of surgical wounds
	Petechiae
	Purpura

that might seem trivial to a patient but should be important to the investigator because it might provide insight into the location of the cough trigger.

QUALITY OF LIFE QUESTIONNAIRES

Quality of life questionnaires specific for the evaluation of the impact of chronic cough^{67,68} provide subjective measurements that are likely to reflect the severity of cough from the viewpoint of the patient. Such measurements integrate both the impact of frequency and the intensity of cough. The LCQ uses a seven-point Likert response scale for 19 items from three domains (physical, psychological, and social) and is shown to be repeatable and sensitive in patients with chronic cough.⁷⁷ This is increasingly becoming a useful clinical tool.

DIAGNOSIS AND INVESTIGATIONS OF CHRONIC COUGH

The history and examination will sometimes indicate the likely associated diagnosis or diagnoses, and the timing of various investigations may vary according to presentation (Table 30-3). Initial investigations may be limited to a chest radiograph, particularly in a cigarette smoker. Abnormalities have been reported in 10% to 30% of chest radiographs of cigarette smokers, although the yield of tumors is likely to be lower. Further investigations (e.g., *computed tomography* [CT] or fiberoptic bronchoscopy) may be pursued despite a “normal” chest radiograph.

Patients on *angiotensin-converting enzyme* (ACE) inhibitor therapy should discontinue such therapy, with replacement by other appropriate treatments. Patients who provide a good history of an upper respiratory tract infection may be observed for 3 to 4 weeks before further investigation or therapeutic trial, although institution of an anti-inflammatory therapy such as inhaled corticosteroids can be useful in controlling this type of cough.

Table 30-3 Diagnostic Evaluation of Chronic Cough

1. History and physical examination.
2. Chest radiograph, particularly in smokers.
3. Initial evaluation may lead to diagnosis of chronic bronchitis in cigarette smokers and of angiotensin-converting enzyme inhibitor cough. Discontinue cigarette smoking and offending drug.
4. Further diagnostic evaluation on basis of initial evaluation:
 - i. If suggestive of postnasal drip, order a CT scan of sinuses, and allergy tests.
 - ii. If suggestive of asthma, request a record of peak expiratory flow measurements at home for 2 weeks and a bronchoprovocation test with histamine or methacholine and/or a trial of antiasthma treatment.
 - iii. If suggestive of gastroesophageal reflux disease, request 24-hour pH monitoring and, if necessary, an endoscopic examination of the esophagus or a barium swallow series.
 - iv. If the chest radiograph is abnormal, consider examination of sputum and a fiberoptic bronchoscopy. A high-resolution CT scan of the thorax and further lung function evaluation may be necessary.
5. Treat specifically for associated conditions. The cause(s) of cough is (are) determined when specific therapies eliminate or improve the cough. There may be more than one associated cause for the cough.

After these initial steps, investigation of the major causes of cough should be considered. Postnasal drip (“nasal catarrh” or “upper airway cough syndrome”), asthma, and GERD are the three most common conditions associated with a chronic cough, and a diagnostic approach to exclude these conditions is sensible. Postnasal drip, secondary to rhinosinusitis, is an often overlooked condition. If there is a history of postnasal drip or rhinosinusitis, examination of the nose and sinuses with a computed axial tomogram of the sinuses may be indicated. Treatment consists of corticosteroid nasal drops together with an antihistamine, with the possibility of adding antibiotic therapy and a short period of treatment with a nasal decongestant. An asthma diagnosis is supported by the presence of diurnal variation in peak flow measurements, bronchial hyperresponsiveness to histamine or methacholine challenge, and the presence of eosinophils in sputum. Under the umbrella of “asthma” would also be included cough-variant asthma and eosinophilic bronchitis. However, a therapeutic trial with inhaled corticosteroids may be the best initial approach, particularly when the history and examination provide supportive clues. It is important that effective doses of medication over a sufficient period of time are given. Often, a longer-than-usual period of treatment is necessary to control the cough, and GERD may be initially evaluated with ambulatory esophageal pH monitoring.

Often, more than one of these conditions may coexist and cough may respond only with concomitant treatment of these. For example, inhaled steroid therapy and gastric acid suppression with a proton pump inhibitor or H₂-histamine blockers would be indicated for the coexistence of asthma and GERD, respectively.

Bearing in mind that there are a myriad of other less common causes of a chronic cough, investigations must proceed further if the common causes have been excluded. Lung function tests to include lung volumes and diffusing capacity, as well as a CT of the lungs, should be considered in case of bronchiolar or parenchymal disease or unsuspected bronchiectasis. Fiberoptic bronchoscopy should be considered and, apart from excluding small central tumors, provides mucosal biopsies for histologic diagnosis (e.g., to diagnose eosinophilic bronchitis).

CAUSES AND TREATMENT OF ACUTE AND CHRONIC COUGH

ACUTE COUGH

Acute cough is usually due to a viral or bacterial upper respiratory tract infection. The cough of the common cold is usually self-limiting and accompanies the cold in the majority of sufferers within the first 48 hours.⁷⁸ Other symptoms of postnasal drip, throat-clearing, irritation of the throat, sore throat, nasal obstruction, and nasal discharge also accompany the cough, which usually resolves within 2 weeks, although it can be sometimes prolonged. Pertussis should be considered in the differential diagnosis, particularly with a whooping characteristic of the cough (Audios 30-3 and 30-4), and is often associated with vomiting. About 20% of adolescents and adults with cough

lasting for 2 weeks or more have evidence of recent whooping cough.⁷⁹ Other causes of acute cough are pneumonia, congestive cardiac failure, exacerbation of *chronic obstructive pulmonary disease* (COPD), aspiration, or pulmonary embolism. These conditions are usually accompanied by other symptoms such as shortness of breath and fever, but cough may remain the predominant or, rarely, the only symptom.

Patients with the common cold usually self-medicate with over-the-counter antitussive preparations. A Cochrane review reported no good evidence for or against the effectiveness of over-the-counter medicines such as antitussives and antihistamines in acute cough. “Satisfactory” responses to pediatric cough syrups were reported in 46% and 56% of children compared with 21% of children in the placebo group.⁸⁰ Codeine was ineffective compared with placebo against the acute cough of the common cold,⁸¹ while dextromethorphan had some effect in a meta-analysis,⁸² but not in two smaller studies.^{83,84} In a study of 100 children, dextromethorphan or diphenhydramine given as a single dose before bedtime was found to be no better than placebo in providing nocturnal symptom relief for children with cough and sleep difficulty from an upper respiratory tract infection.⁸⁵ Instead, a subsequent study showed that buckwheat honey provided symptomatic relief,⁸⁶ but a placebo effect was not excluded. The American Academy of Pediatrics has highlighted the fact that the efficacy of antitussive preparations in children is lacking and that these medications may be potentially harmful.⁸⁷ Their recommendation is that cough due to acute viral airway infections is self-limiting and should be treated only with fluids and humidity.

A first-generation antihistamine and decongestant has been proposed for the treatment of cough associated with a postnasal drip in acute cough,⁷⁸ but a study using a newer-generation antihistamine, loratadine, in combination with a decongestant showed no effect.⁸⁸ The rhinitis associated with the common cold may become mucopurulent, but this is not an indication for antibiotic therapy unless this persists for more than 10 to 14 days.

CHRONIC COUGH

Chronic cough (cough that persists for more than 3 weeks) can be caused by many diseases, but according to several series, it is most commonly due to postnasal drip, asthma, GERD, chronic bronchitis, and bronchiectasis.^{73,89} A recent worldwide survey revealed a striking gender and age demographic of chronic coughers, most of whom are female aged between 60 and 69 years.^{89a}

Postnasal Drip (Rhinosinusitis, Upper Airway Cough Syndrome)

Postnasal drip has been reported as being the most common cause of chronic cough.^{89,90} The *upper airway cough syndrome* (UACS) has been coined as a better term than postnasal drip to denote chronic cough related to upper airway abnormalities. The strong association between postnasal drip and chronic persistent cough is based on epidemiologic evidence and on a prospective study in adults. Postnasal drip (“nasal catarrh”) is characterized by a sensation of nasal secretions or of a “drip” at the back of the throat,

accompanied often by frequent need to clear the throat (“throat-clearing”). There may be a nasal quality to the voice due to concomitant nasal blockage and congestion, and there may be hoarseness of the voice. Physical examination of the pharynx is often unremarkable, although a “cobblestoning” appearance of the mucosa and draining secretions may be observed. CT of the nasal passages and sinuses may reveal rhinosinusitis with mucosal thickening or sinus opacification and air-fluid levels. Extrathoracic variable upper airway obstruction is not always present.⁹¹ Testing for allergens may be helpful, and the presence of allergy to pollens supports the presence of seasonal allergic rhinitis.

The best treatment is topical administration of corticosteroid drops in the head-down position, often with the concomitant use of antihistamines. Topical steroids offer a local effect with the minimum of side effects. Occasionally, severe symptoms may be controlled initially by a short course of oral steroids, followed by topical therapy. A topical anticholinergic spray to the nose (such as ipratropium bromide) to dry excessive nasal secretions may provide additional benefit. A combination of topical corticosteroid, antihistamine, and anticholinergic treatments has been shown to benefit the chronic cough accompanying postnasal drip associated with an improvement in nasal discharge and endoscopic appearances.⁹² Topical decongestant vasoconstrictor sprays may be useful adjunct therapy for a few days, but rebound nasal obstruction may develop after prolonged use. Antibiotic therapy is necessary in the presence of acute sinusitis involving bacterial infection with the presence of mucopurulent secretions that has persisted for at least 10 days.

Asthma and Associated Eosinophilic Conditions

Asthma may lead to chronic cough under different clinical settings. Asthma may present predominantly with cough, often nocturnal, and the diagnosis is supported by the presence of reversible airflow limitation and bronchial hyperresponsiveness.⁹³ This condition of “cough-variant” asthma is a common type of asthma in children. Elderly asthmatics may also give a history of chronic cough before a diagnosis of asthma. Cough as the only presenting symptom of asthma has been reported in up to 57% of patients and is often its most prominent symptom.⁹⁴ Cough may also arise as a first sign of worsening of asthma; the cough usually presents first at night, associated with other symptoms such as wheeze and shortness of breath with drops in early morning peak flows. Some patients with asthma may also develop a persistent dry cough despite good control of their asthma.

Atopic cough is recognized in Japan as an isolated chronic cough characterized by an atopic background, sputum eosinophilia, cough hypersensitivity, normal pulmonary function, and airway hyperresponsiveness.⁹⁵ On the other hand, eosinophilic bronchitis is characterized by cough without asthma symptoms or bronchial hyperresponsiveness but with eosinophilia in sputum.⁹⁶

An enhanced cough reflex, although not usually found in patients with asthma, may be seen in a subgroup of asthmatics with a persistent cough.⁹⁷ In these patients, cough sensors may be sensitized by inflammatory mediators such as bradykinin, tachykinins, and prostaglandins. Cough

in asthma may also be due to bronchial smooth muscle contraction, which may activate cough receptors through physical deformation. Indeed, in some patients with cough-variant asthma, β -adrenergic bronchodilators are effective antitussives.⁹⁸ A predominance of eosinophils in induced sputum and bronchial biopsies, together with a thickened basement membrane and bronchial hyper-responsiveness, is present in cough-variant asthma. In eosinophilic bronchitis, conversely, cough responsiveness to capsaicin is increased without bronchial hyper-responsiveness, but the immunopathologic abnormalities are similar to those of asthma.⁹⁹

Cough associated with asthma should be treated with antiasthma medication including inhaled corticosteroid therapy and bronchodilators such as β_2 -adrenergic agonists. Such treatment should be given over a prolonged period of time (3 to 6 months) at the lowest dose that controls the cough. Often, a trial of oral corticosteroids (e.g., prednisolone 40 mg/day for 2 weeks) may be recommended, particularly in those asthmatics who have had a cough despite being on adequate antiasthma medication. A combination of inhaled corticosteroids and a long-acting β -agonist is now the best available maintenance treatment for moderate-to-severe asthma. Leukotriene receptor antagonists may also control cough-variant asthma.¹⁰⁰ Eosinophilic bronchitis responds well to inhaled or oral corticosteroid therapy.

Gastroesophageal Reflux Disease

GERD, the movement of acid and other components of gastric contents from the esophagus into the larynx and trachea, is one of the most commonly associated causes of chronic cough in all age groups. GERD may lead to symptoms such as heartburn, chest pain, a sour taste, regurgitation, and a chronic persistent cough. Prolonged exposure of the lower esophagus to acid may lead to esophagitis, Barrett esophagus, esophageal ulceration and stricture, and bleeding. However, there may also be no symptoms associated with GERD or with the exposure of the esophagus to acid. An esophageal-tracheobronchial cough reflex mechanism has been proposed on the basis of studies in which perfusion of the distal esophageal with acid induced coughing episodes that could be suppressed by local distal esophageal perfusion of lidocaine and by an inhaled anticholinergic agent, ipratropium bromide.¹⁰¹ More than 90% of the cough episodes have been shown to be temporally related to reflux episodes. Significant reflux happens in both supine and upright positions. Given the poor response of cough to treatment with gastric acid suppressors such as proton pump inhibitors,^{102,103} there is a possibility that non-acid reflux factors such as the liquid, gas, pepsin, or other enzymes may be important in stimulating cough. A high proportion of patients with GERD also appear to have laryngopharyngeal reflux,¹⁰⁴ which may represent a direct effect of gastroesophageal reflux on cough receptors in the larynx and trachea. However, one study showed no differences in non-acid reflux events in the proximal or distal esophagus between patients with chronic cough and normal subjects.¹⁰⁵ Coughing itself may precipitate reflux, creating a vicious circle of acid-inducing cough that in turn induces acid reflux. Continuous monitoring of tracheal and

esophageal pH in patients with symptomatic GERD has demonstrated significant increases in tracheal acidity with a fall in the pH to 4 or less during episodes of reflux.¹⁰⁶ Other components of the refluxate, apart from acid, such as pepsin or other enzymes may also contribute to cough.

There is no particular pattern of the cough caused by GERD. The cough may be long-standing and productive. In the presence of reflux and microaspiration, laryngeal symptoms may be present with dysphonia, hoarseness, frequent throat clearing, a globus sensation (e.g., a feeling of a lump in the throat), and sore throat; often, posterior vocal cord laryngeal inflammation with edema, erythema, contact ulceration, pachydermia, and/or granuloma is visible. There may be associated esophageal dysmotility characterized by heartburn, water brash, and oral regurgitation, which can be worse in the supine position. Ineffective esophageal peristalsis has been reported in chronic cough, and this may increase the exposure time of the larynx and pharynx to any refluxate.^{107,108}

Monitoring of 24-hour ambulatory pH, examining for episodes of pH below 4, together with monitoring of non-acid reflux in the proximal and distal esophagus with analysis of the temporal relationship between cough and reflux episodes, are the most specific tests for GERD. In one study of patients with chronic cough, however, acid reflux preceded cough in only up to 13% of coughs; however, many of the patients did have reflux, suggesting that the association may be more indirect.¹⁰⁹ Positive predictive values for the use of esophageal pH monitoring are reported to be between 68% and 100%, and a negative test nearly excludes GERD as the cause of cough. However, there has been a greater association of a cough event with a non-acid reflux episode in chronic cough patients.¹¹⁰ In half of an unselected cohort of patients with chronic cough, a positive association for acid reflux detected by esophageal pH testing and for non-acid reflux detected by intraluminal impedance and cough sounds on an ambulatory cough counter was reported. This was associated with a heightened cough reflex sensitivity.¹¹¹ Other tests that may be used are esophageal manometry to measure dysmotility, particularly associated with reflux episodes; upper gastrointestinal contrast series to detect reflux of barium into the esophagus; or an upper gastrointestinal endoscopy. A trial of antireflux treatment with a proton pump inhibitor or a histamine H_2 -antagonist may be used in patients as a diagnostic measure where ambulatory 24-hour pH esophageal monitoring is not available. This may also be indicated in patients with chronic cough that remains unexplained after diagnostic workup or exclusion of other associated causes.

The aim of treatment of GERD is to decrease the frequency and duration of the events. Conservative measures such as weight reduction, a high-protein, low-fat diet, elevation of the head of the bed, and avoidance of coffee and smoking should be advocated. Reduction of acid production by the stomach can be achieved with either H_2 -histamine blockers or proton pump inhibitors, although they have not been compared. Given the increasing use of proton pump inhibitors and their superior effect in acid suppression and in treating GERD, these drugs will remain the preferred choice. Although initial uncontrolled studies

have provided optimistic effects of histamine H₂-receptor antagonists or proton pump inhibitors in controlling the cough associated with GERD, double-blind placebo-controlled studies^{103,112} report more limited effects. Nevertheless, treatment for 3 months, at the highest recommended dose of a proton pump inhibitor, is usually advocated. It has been reported that those with evidence of a pathologic acid reflux may profit more from PPI therapy.¹¹³ The effect of specific treatments for esophageal dysmotility is not known. A case report of successful treatment of cough in 3 patients with GERD unresponsive to PPI using baclofen was reported,¹¹⁴ with baclofen perhaps working through reducing both acid and non-acid reflux. The use of domperidone to increase gastric emptying in GERD remains unclear.

One of the reasons for failure of an antacid strategy may be the continued effect of the nonacid refluxate. Antireflux surgery such as laparoscopic fundoplication may be considered for patients with proven GERD disease whose cough has failed to respond to medical therapy.¹¹⁵ Complete resolution of the cough has been reported in about 60% of subjects,¹¹⁶ but predictors of a good response to surgery have not been defined.

Chronic Bronchitis/Chronic Obstructive Pulmonary Disease

Chronic bronchitis should be considered in a patient who produces sputum on most days over at least 3 consecutive months, particularly during the winter months, over at least 2 consecutive years. Although 30% to 40% of the community smokes tobacco, chronic bronchitis is only reported in 5% of the patients seeking medical attention for cough. In a smoker, the presence of chronic bronchitis may be predictive of progressive irreversible airflow obstruction, leading to COPD.¹¹⁷ In addition, the presence of cough and sputum in COPD identifies patients at greater risk of subsequent exacerbations.¹¹⁸

The cough of chronic bronchitis may result from excessive sputum production associated with mucus cell hyperplasia and bronchiolar inflammation. In addition, there is evidence of an increase in capsaicin cough hypersensitivity in patients with COPD,^{97,119} which may result from the airway inflammatory process. The presence of airflow obstruction diagnosed on the basis of a ratio of *forced expiratory volume in 1 second* to *forced vital capacity* (FEV₁/FVC) of less than 70% or of an FEV₁ of less than 70% of the predicted value indicates the presence of COPD.¹²⁰

The productive cough in chronic bronchitis is exacerbated by upper respiratory infections with common viruses or respiratory bacteria or by exposure to irritating dusts or environmental pollutants. Other causes of productive cough such as bronchiectasis or postnasal drip should be excluded. It is important to exclude also the presence of lung tumors. Cessation of cigarette smoking is usually accompanied by a reduction in cough, most often within 4 to 5 weeks.¹²¹ Smoking cessation may be aided by various adjuncts such as nicotine replacement or bupropion or varenicline, a nicotine receptor partial agonist.¹²² Treatment of any associated chronic airflow obstruction with short-acting and/or long-acting β_2 -adrenoceptor agonists and anticholinergic agents should be considered, particularly in

the presence of dyspnea. Suppression of the inflammatory process in the small airways may be tried with the combination of inhaled corticosteroids and long-acting β -agonists. Oral or systemic corticosteroids are effective in the treatment of exacerbations of COPD. Mucolytic therapy may reduce the incidence of exacerbations. Indirect (symptomatic) antitussive therapies are not recommended but may be needed in patients with excessive coughing that is impairing their quality of life.

Bronchiectasis

The cough of bronchiectasis is associated with overproduction of airway secretions together with a reduced clearance, often within a vicious circle of recurrent bacterial infections. Usually, the patient produces 30 mL or more of mucoid or mucopurulent sputum per day, sometimes accompanied by fever, hemoptysis, and weight loss. Early on, bronchiectasis may present solely as a persistent, productive cough. Bronchiectasis may be associated with postnasal drip and rhinosinusitis, asthma, GERD disease, and chronic bronchitis. Common pathogens cultured from sputum include *Haemophilus influenzae*, *Staphylococcus aureus*, and *Pseudomonas aeruginosa*. The chest radiograph may show increased bronchial wall thickening, particularly in the lower lobes in advanced cases, but thin-section CT of the chest can reveal early changes of airway wall thickening, dilation, and distortion, with mucus plugging, and evidence of bronchiolitis.¹²³

Cough in bronchiectasis is the most effective mechanism for clearing airway secretions. Chest physiotherapy to improve airway clearance remains essential. In addition, there is an increased capsaicin cough response in bronchiectasis.¹²⁴ Cough during infective exacerbations of bronchiectasis may become a tiring symptom. Long-term macrolide therapy may lead to an improvement in exacerbations and lung function. The cough due to bronchiectasis may be controlled by the use of inhaled β_2 -agonists to improve mucociliary clearance and reverse any associated bronchoconstriction, by postural drainage of airway secretions, and by the use of intermittent antibiotic therapy. Use of antitussives is not recommended but, in the context of severe cough, some suppressive effect may be clinically beneficial.

Angiotensin-Converting Enzyme Inhibitor Cough

ACE inhibitors are often prescribed for the treatment of hypertension and heart failure, and cough has been observed in 2% to 33% of patients.^{125,126} The cough is typically described as "dry," associated with a tickly irritating sensation in the throat. It may appear within a few hours of taking the drug, but it may also become apparent only after taking the drug for weeks or even months. The cough disappears within days or weeks following withdrawal of drug. Patients with ACE inhibitor cough demonstrate an enhanced response to the capsaicin inhalation challenge. Accumulation of bradykinin and prostaglandins, which sensitize cough receptors directly, has been implicated. The best course of action for ACE inhibitor cough is to discontinue the treatment and replace it with alternative therapies such as angiotensin II receptor antagonists, which are not usually associated with cough.

Postinfectious Cough

Postinfectious cough has been reported in 11% to 25% of patients with chronic cough.^{127,128} A persistent cough develops in 25% to 50% of patients following *Mycoplasma* or *Bordetella pertussis* infection.¹²⁹ *B. pertussis* infection has now been increasingly recognized as a cause of both acute and chronic cough, particularly in older children and adults.¹³⁰ In children, other respiratory infections associated with chronic cough include viruses (respiratory syncytial virus and parainfluenzae), *Mycoplasma*, and *Chlamydiae*.¹³¹ The cough of *B. pertussis* usually lasts for only 4 to 6 weeks (but can last longer) and is spasmodic with a typical whoop. In most patients with a postinfectious cough, the initial trigger is usually an upper respiratory tract infection, and cough that would have been expected to last for only a week persists for many months. Such patients are often referred to a cough clinic and are usually investigated for the more commonly associated cause of cough. It is assumed that the initial infection may have induced persistent airway inflammation or epithelial damage that then allowed irritants to penetrate more easily, thereby setting up a vicious circle of events that maintains and triggers further cough.

Inhaled corticosteroids are often prescribed, but with variable success. Oral steroids may be successful.¹²⁷ Inhaled ipratropium bromide was reported to be effective in a small study.¹³² Macrolide antibiotics or trimethoprim/sulfamethoxazole are effective in eliminating *B. pertussis* but do not alter the subsequent clinical course.¹³³

Other Conditions

Other conditions causing cough include bronchogenic carcinoma, metastatic carcinoma, sarcoidosis, chronic aspiration, interstitial lung disease, or left ventricular failure, conditions that can usually be excluded with a normal chest radiograph. More recently, associations of chronic cough with obstructive sleep apnea, chronic tonsillar enlargement, and laryngeal dysfunction have been reported. Psychogenic or habit cough is common, particularly in children, and is usually a diagnosis arrived at after exclusion of other causes. Habit cough is a throat-clearing noise made by a person who is nervous and self-conscious. Cough may be associated with a depressive illness, and long-standing cough may cause depression. In the pediatric population, other cough etiologies specific for this age group need to be considered: congenital abnormalities including vascular rings and tracheobronchomalacia (eFig. 30-1), pulmonary sequestration or mediastinal tumors, foreign bodies in the airway (eFig. 30-2) or esophagus, aspiration due to poor coordination of swallowing or esophageal dysmotility, and heart disease.

Chronic Persistent Cough of Unknown Cause ("Idiopathic" Cough)

Identification of a potential cause of cough has been reported in 78% to 99% of patients presenting at a cough clinic, and specific treatment of identifiable causes has also been reported to be successful in up to 69% to 99% of cases.^{89,134} However, more recent series have identified 7% to 46% of patients with chronic cough as having idiopathic cough, despite undergoing thorough diagnostic evaluation.

These differences may relate to the definition of successful treatment and the case mix. The patient with idiopathic cough should be diagnosed as such only after an intensive diagnostic evaluation and empirical trial of therapy(ies) have been carried out. In one report, patients with idiopathic cough tended to be middle-aged women who frequently gave a history of cough onset at menopause and had associated autoimmune disorders such as autoimmune hypothyroidism.¹³⁵ Patients with an enhanced cough reflex often complain of a persistent tickling sensation in the throat that leads to paroxysms of coughing. This sensation can be triggered by factors such as changes in ambient temperature, taking a deep breath, laughing, talking over the phone for a few minutes, and exposure to cigarette smoke or other irritants such as aerosol sprays or perfumes or to certain odors. Mucosal biopsies taken from a group of nonasthmatic patients with idiopathic cough showed increased mast cell numbers and features of airway wall remodeling such as increased sub-basement membrane thickening, increased airway smooth muscle mass, goblet cell hyperplasia, and increased blood vessels.¹³⁶ These changes could represent the sequelae of chronic trauma to the airway wall following intractable cough and could in turn lead to sensitization of the cough reflex. There is an increase in neural profiles that express the neuropeptide, *calcitonin gene-related peptide* (CGRP), and the calcium channel, TRPV1, in the airway epithelium of chronic coughers that could contribute to the increased cough reflex.^{137,138}

Cough Hypersensitivity Syndrome

The concept of a *cough hypersensitivity syndrome* (CHS) has been introduced to encompass most chronic coughs, particularly those with a definition of an idiopathic cough.^{55,139,139a} This concept focuses on the pathogenesis of the cough itself and may be defined as a neuropathic syndrome presenting with a chronic persistent cough that has lasted for more than 8 weeks and is associated with characteristic trigger symptoms and sensations indicating the presence of an enhanced cough reflex (see Fig. 30-6). Patients with CHS often complain of a persistent tickling or irritating sensation in the throat (feeling of an itch) or a choking sensation, and it may sometimes be felt in the chest, which often leads to paroxysms of uncontrollable coughing. Other symptoms associated with chronic cough patients include clearing of the throat, chest tightness, hoarse voice and dysphonia, vocal cord dysfunction symptoms, sensation of globus, acid reflux symptoms, sense of effort, and air hunger. Triggers such as lying down, eating, singing, talking, laughing, and taking a deep breath (through mechanoreceptors); changes in ambient temperature (through thermoactivation); aerosols, scents, odors, and cigarette smoke (through chemoactivation) are common.¹⁴⁰ In addition to these symptoms, patients with chronic cough demonstrate cough hypersensitivity with inhaled citric acid or capsaicin challenge.

Within CHS, the sensory laryngeal neuropathy described by laryngologists can be included as a condition presenting with chronic cough, laryngospasm, or paradoxical vocal cord dysfunction.¹⁴¹ This has been described after an upper respiratory virus infection affecting the superior or recurrent laryngeal nerves. An irritable larynx measured as laryngeal hyperresponsiveness with histamine inhalation is

present in the majority of chronic cough patients associated with postnasal drip, GERD, and asthma, and with unexplained cough.¹⁴² Paradoxical vocal cord movement present in chronic cough is also associated with extrathoracic airway hyperresponsiveness.¹⁴³

COUGH SUPPRESSION THERAPIES

NONPHARMACOLOGIC APPROACH: SPEECH PATHOLOGY MANAGEMENT

In patients with chronic cough refractory to medical treatment, speech pathology management or cough suppression therapy consisting of an educational component about cough, cough suppression therapy, vocal hygiene training, and psychoeducational counseling has been shown to be effective in improving cough symptom scores, as well as breathing, voice, and upper airway symptoms.¹⁴⁴ In addition, this therapy also reduced capsaicin cough sensitivity.¹⁴⁵ Improved cough and breathing symptoms were also observed in patients with chronic cough and paradoxical vocal cord movement after a combination of proton pump inhibitor therapy and a speech pathology intervention.¹⁴⁶ This treatment administered by a voice and speech and language specialist or respiratory physiotherapist should be considered for patients with refractory chronic cough.¹⁴⁷

“SYMPTOMATIC,” “INDIRECT,” OR “NONSPECIFIC” ANTITUSSIVES

When the treatment of the cause of cough is not effective or not available, therapies directed at eliminating the symptom of cough irrespective of the cause of the cough may be tried¹⁴⁸ (Table 30-4). These therapies are also termed “symptomatic,” “indirect,” or “nonspecific” antitussives. This is particularly relevant to patients with lung cancer with a persistent cough, of whom 50% rate their cough as moderate to severe.¹⁴⁹ Drugs that affect the complex mechanism of the cough reflex may work by inhibition of central mechanisms within the brain stem or of peripheral mechanisms on the cough sensors in the airways. Alternatively, antitussive activity of some drugs may not be a result of pharmacologic means because cough exhibits an unusually robust sensitivity to placebo suppression.^{16,150} Because of the relative low efficacy of current antitussives, several new classes of antitussives are being developed on the basis of our understanding of the cough reflex and of the membrane receptors and channels on cough sensors.^{151,152} An ideal cough therapy would be one that suppresses excessive cough in disease yet allows for protective cough to be maintained. No such compounds have been identified to date. A summary of the existing direct and indirect antitussives and their potential modes and sites of actions is shown in Figure 30-7.

NARCOTIC AND NON-NARCOTIC ANTITUSSIVES

Opiates including morphine, diamorphine, and codeine are the most effective antitussive agents. (Diamorphine is not prescribed in the United States.^{152a}) At their effective doses, they cause physical dependence, respiratory depression,

Table 30-4 Treatments for Cough

1. TREATING THE SPECIFIC UNDERLYING CAUSE(S)	
Asthma, cough-variant asthma	Bronchodilators and inhaled corticosteroids
Eosinophilic bronchitis	Inhaled corticosteroids; leukotriene inhibitors
Allergic rhinitis and postnasal drip	Topical nasal steroids and antihistamines Topical nasal anticholinergics (with antibiotics, if indicated)
Gastroesophageal reflux	Conservative measures Histamine H ₂ antagonist or proton pump inhibitor
Angiotensin-converting enzyme inhibitor	Discontinue and replace with alternative drug such as angiotensin II receptor antagonist
Chronic bronchitis/COPD	Smoking cessation Treat for COPD
Bronchiectasis	Postural drainage Treat infective exacerbation and airflow obstruction
Infective tracheobronchitis	Appropriate antibiotic therapy Treat any postnasal drip
2. SYMPTOMATIC TREATMENT (ONLY AFTER CONSIDERATION OF CAUSE OF COUGH)	
Acute cough likely to be transient (e.g., upper respiratory viral infection)	Simple linctus (cough syrup)
Persistent cough, particularly nocturnal	Opiates (codeine or pholcodeine)
Persistent intractable cough due to terminal incurable disease	Opiates (morphine or diamorphine) Local anesthetic aerosol
Cough in children	Simple linctus (pediatric)

and gastrointestinal colic. Morphine and diamorphine are reserved for the control of cough and pain of terminal bronchial cancer patients, but codeine, dihydrocodeine, and pholcodeine can be tried in other cases of chronic cough. Codeine is the methylether of morphine and has long been the standard centrally acting antitussive drug against which the pharmacologic and clinical effects of newer drugs have been measured. Codeine is probably the most commonly prescribed antitussive. It has some antitussive activity, compared with placebo when given orally. Although codeine possesses antitussive activity against pathologic cough¹⁵² and against induced cough in normal volunteers,¹⁵³ a recent study suggested, contrary to earlier evidence, that it had little effect on cough in selected COPD patients¹⁵⁴ or against acute cough of the common cold⁸¹ compared with placebo.

Codeine should be used cautiously in patients with reduced hepatic function but can be used without dose modification in patients with renal failure. Drowsiness may be an incapacitating side effect, together with nausea, vomiting, and constipation. Rarely, allergic cutaneous reactions such as erythema multiforme have been described. Codeine can cause physical dependence, but on a smaller scale than morphine. Dihydrocodeine has no particular advantage over codeine and may cause more addiction than codeine. Pholcodeine is also as effective as codeine but has little or no analgesic effect.

Morphine and diamorphine (diamorphine is not prescribed in the United States) should be used only for severe

Figure 30-7 Afferent pathways of the cough reflex and some potential sites of action of direct and indirect antitussive therapies. Drugs may be divided according to their peripheral effects on airways or their central effects in the central nervous system (CNS). LTD₄, leukotriene D₄; NK, neurokinin; nTS, nucleus tractus solitarius; PPI, proton pump inhibitor; RAR, rapidly adapting receptors; VRG, ventral respiratory group. (Redrawn and modified from Chung KF: Management of cough. In Chung KF, Widdicombe JG, Boushey HA, editors: Cough: causes, mechanisms and therapy. Oxford, 2003, Blackwell, pp 283–297.)

distressing cough that cannot be relieved by other less potent antitussives and are therefore usually confined to patients with terminal illness such as bronchial carcinoma.¹⁴⁹ Slow-release morphine has been shown to be partially effective in controlling severe chronic cough without altering the cough reflex response.¹⁵⁵ These opioids also relieve anxiety and pain. They cause sedation, respiratory depression, and constipation. Opioids can exacerbate wheezing through the release of histamine, but this is rare. Diamorphine may be preferred to morphine because of its lower incidence of nausea and vomiting.

Dextromethorphan is a non-narcotic antitussive, a synthetic derivative of morphine with no analgesic or sedative properties, and is usually included as a constituent of many compound cough preparations sold over the counter. It is as effective as codeine in suppressing acute and chronic cough when given orally,^{152a,156,157} with one study showing its superiority over codeine.¹⁵⁸ Antitussive efficacy of a single 30-mg dose has been demonstrated against cough associated with upper respiratory tract infections in adults.⁸² However, in children, dextromethorphan has been shown to be ineffective in cough due to upper respiratory tract

infections.^{85,86} It is commonly used as a constituent of many compound cough preparations that are sold over the counter. Side effects are few at the usual dose but, at higher doses, dizziness, nausea, vomiting, and headaches may be reported. It should be avoided in patients with hepatic insufficiency because metabolic degradation takes place in the liver. The American Academy of Pediatrics has highlighted the potential adverse effects and overdosage associated with antitussive preparations containing dextromethorphan in children,⁸⁷ where it is not effective in cough due to upper respiratory tract infections.^{85,86} Dextromethorphan should be used with caution in patients on monoamine oxidase inhibitors in whom central nervous depression and death has been reported.

Other non-narcotic preparations include noscapine and levopropoxyphene, although their antitussive efficacy has not been proved. Levodropropizine, a nonopioid antitussive with peripheral inhibition of sensory cough receptors, has a favorable benefit/risk profile compared with dextromethorphan.^{152a,159} Other drugs acting on cough receptors include benzonatate, which inhibits vagal stretch lung receptors, with a possible central effect.

OTHER NON-NARCOTIC ANTITUSSIVES

Amitriptyline and gabapentin have been used as antitussives. A prospective, randomized, controlled open trial comparing the effectiveness of amitriptyline versus codeine/guaifenesin for chronic cough following an upper respiratory tract infection showed that amitriptyline led to a complete response of the cough in most subjects while none of the codeine/guaifenesin group had a complete response.¹⁶⁰ Gabapentin was effective in reducing cough in chronic cough patients in a randomized double-blind trial, suggesting that there is a central reflex sensitization in refractory chronic cough.¹⁶¹ Both amitriptyline and gabapentin have central antinociceptive actions, and both have been used successfully in the treatment of neuropathic pain. Gabapentin may reduce pain via an action on gamma-aminobutyric acid neurotransmission or voltage-gated ion channels in the spinal cord, midbrain, thalamus, and insular cortices in the brain. The success of these agents in controlling chronic cough may indicate that chronic cough is a neuropathic condition.⁵⁵

LOCAL ANESTHETICS

Lidocaine aerosol inhaled from a nebulizer has been administered to cases of intractable cough with variable results and should be reserved for selective individual cases.¹⁶² It works by inhibiting sensory neural activity but also removes reflexes that protect the lung from noxious substances. Its effects are transient and should be avoided in patients with asthma or a past history of asthma because they can induce severe bronchoconstriction. There have been no controlled trials of local anesthetics, but their efficacy in controlling cough is not ideal because of their short duration of effect. A retrospective analysis suggests that nebulized lidocaine may be a safe option and that a 2-week trial may identify those patients who will derive most therapeutic benefit.¹⁶³

EXPECTORANTS AND MUCOLYTICS

Expectorants and mucolytics may alter the volume of secretions or their composition. Despite the lack of proof, mucolytic agents such as acetylcysteine, carbocysteine, bromhexine, and methylcysteine are often used to facilitate expectoration by reducing sputum viscosity in patients with chronic bronchitis. A small reduction in the exacerbation of bronchitis has been reported with oral acetylcysteine, accompanied by small improvement in cough, a decrease in volume of sputum, and some ease of expectoration. Aromatic agents such as eucalyptus and menthol have decongestant effects in the nose and can be useful in short-term relief of cough. Menthol inhibits capsaicin-induced cough in normal volunteers¹⁶⁴ and acts on a cold-sensitive receptor. Demulcents also form an important component of many proprietary cough preparations and may be useful because the thick sugary preparation may act as a protective layer on the mucosal surface.

POTENTIAL NEW ANTITUSSIVES

New cough suppressants in development include new opioids or blockers of ion channels on vagal afferent

endings,¹⁶⁵ but as yet few have been tested in humans. An orally active selective NOP1 (*nociceptin opioid 1*) receptor agonist was tested in subacute cough with no significant subjective or objective efficacy compared with placebo.¹⁶⁶ Preclinical studies have identified TRP channels as an exciting target for cough suppression. TRPV1 agonists are potent inducers of cough,¹⁶⁷ and patients with chronic cough have increased TRPV1-positive nerve fibers in their airways. TRPV1 antagonists are currently being developed for control of pain, and several compounds have been examined in man.¹⁶⁸ However, early trials with TRPV1 blockers in cough patients have been disappointingly negative.^{168a} Hyperthermia and noxious heat sensation are among the adverse effects of these TRPV1 antagonists, which has limited their use. Agonists acting at TRPA1, such as cinnamaldehyde, acrolein, and allyl isothiocyanate (aka mustard oil), can also cause cough, including in humans,¹⁶⁹ and TRPA1 antagonists are currently being tested in cough. Voltage-gated sodium channels are channels that initiate and conduct action potentials. Lidocaine is a nonselective blocker of this family of sodium channels. The NaV1.7 subunit has been found to be specifically involved in the control of cough responses to citric acid in guinea pigs,¹⁷⁰ but as yet there are no specific blockers of NaV1.7. Memantine, the uncompetitive NMDA channel blocker developed for use in Alzheimer disease, inhibits cough in guinea pigs¹⁷¹ and is currently being tested in humans.

Key Points

- Cough may be a sign of disease in or outside the airways and lungs and a useful indicator for both patient and physician for initiating a diagnostic evaluation and treatment of disease processes.
- Impairment or absence of coughing can be harmful or even fatal in disease. On the other hand, when cough itself is persistent and excessive, it can also be harmful and deleterious and may need to be suppressed directly.
- The most sensitive sites for initiating cough are the larynx and tracheobronchial tree.
- In the management of a patient with cough, the first step is to identify the cause(s) of the cough and then treat the cause(s).
- Postnasal drip, asthma, and gastroesophageal reflux are the three most common conditions associated with a chronic cough, and a diagnostic approach to exclude these conditions early on is sensible.
- Many cigarette smokers have a chronic cough, but a change in the pattern or characteristics of their cough, such as an increase in intensity or an accompanying hemoptysis, should force a smoker to seek medical attention. A chest radiograph is mandatory in this situation.
- Patients with chronic cough while on angiotensin-converting enzyme inhibitor therapy should discontinue such therapy, with replacement by other appropriate treatments.
- When the treatment of the cause of cough is not effective, therapies directed at eliminating the symptom of cough irrespective of the cause of the cough may be tried (see Table 30-4).

INTRODUCTION

Pain is a complex subjective experience that varies from person to person in its quality, intensity, duration, location, frequency, and associated features. Its perception is influenced by a subject's culture, emotional and cognitive contributions, socioeconomic status, familial background, prevailing psychological factors, anticipation and previous experience, and the clinical context.

Chest pain is characterized by an unpleasant sensation that is either localized to the thorax or believed to originate from structures located there. It may announce the presence of severe, occasionally life-threatening, disease. Diagnosis of chest pain is often complicated by the vague presentations and indistinct anatomic localization of many of its causes.

EPIDEMIOLOGY

There are uncertainties about the exact prevalence of chest pain. In a study of 500 randomly selected households in Burlington, Canada, 16% of 827 respondents reported experiencing pain within the 2 weeks preceding the survey.¹ Persistent pain was approximately twice as common as temporary pain, and chest pain was the fifth most common type of temporary pain. In studies of acute pain that was sufficient to warrant medical attention, chest pain is always an important factor.

A survey of 1016 randomly selected enrollees of a health care plan in Seattle, Washington, revealed that they reported a high incidence of pain lasting a whole day or more several times during the previous 6 months²; the most common complaint was back pain, followed by headache, abdominal pain, facial pain, and chest pain. Chest pain accounted for 12% of the reported cases but was the most common site of pain that prompted respondents (35%) to seek medical attention. Pain is also a common reason for persons to visit hospital emergency departments. In a survey of 36,271 random evaluations, stomach pain, other abdominal pain,

and chest pain were the most often cited reasons; they presented with almost equal frequency and, together, accounted for 10.7% of all emergency department visits.³

NEUROBIOLOGY OF PAIN

Pain is not a simple sensation. The neurobiologic and functional components of the sensory channels for pain are neither fixed nor immutable. The nervous system, from the level of the nociceptor (the receptor that responds to noxious stimuli) to the supraspinal sites of integration, is characterized by its dynamic response (plasticity) to tissue insult.

Pain arising from *visceral* organs (e.g., heart or gastrointestinal tract) differs in many ways from that arising from *somatic* structures, such as the skin. Visceral pain is difficult to localize, is diffuse in character, and is typically referred to somatic structures. In addition, it is often associated with greater autonomic and motor responses than is somatic pain. These differences between visceral and somatic pain are associated with characteristic features of sensory innervations that are unique to the viscera.

SOMATIC PAIN

Somatic structures, such as the skin, are invested with a wide variety of nociceptors, each with selective sensitivities to mechanical, thermal, or chemical stimuli, in addition to the polymodal nociceptor that responds to multiple modalities of noxious stimuli.^{4,5} Cutaneous nociceptors are characterized by very infrequent or no spontaneous discharges, an ability to encode stimulus intensities in the noxious (but not innocuous) range, and most importantly, sensitization. *Sensitization* refers to an increase in the magnitude of response after tissue insult, sometimes associated with an increase in spontaneous activity as well as a decrease in response threshold. This attribute of nociceptors contributes to development of hyperalgesia, or an increased response to a stimulus that is normally painful.

When a tissue is injured, a host of sensitizing chemicals are synthesized at the site of injury or released from circulating cells that are attracted to the site of injury. These include amines (e.g., histamine and serotonin), peptides (e.g., substance P and calcitonin gene—related peptide), kinins (e.g., bradykinin), neurotrophins, cytokines, prostaglandins, leukotrienes, excitatory amino acids (e.g., glutamate), and free radicals. However, it is unlikely that any one putative chemical mediator is responsible for nociceptor sensitization. Although substance P, for example, is contained in most nociceptor cell bodies, it is also present in a significant number of non-nociceptor cell bodies. Similarly, other neuropeptides, such as calcitonin gene—related peptide, somatostatin, and galanin, are found more commonly in small- to intermediate-sized dorsal root ganglion cell bodies.

VISCERAL PAIN

Input to the central nervous system from aortic baroreceptors, gastric chemoreceptors, and pulmonary stretch receptors is rarely perceived. Nevertheless, it is evident that visceral afferents possess many of the characteristics of nociceptors.

All viscera possess a dual innervation. Organs of the thoracic cavity are innervated by vagal afferent fibers with cell bodies in the nodose and jugular ganglia as well as by spinal afferent fibers with cell bodies in thoracic dorsal root ganglia. Unlike their somatic counterpart, spinal visceral afferent fibers typically traverse either or both prevertebral and paravertebral ganglia en route to the spinal cord. Thus, in contrast to somatic input to the central nervous system, which has a single, usually spinal, destination, input to the central nervous system from organs in the thoracic cavity arrives at two locations, namely the brain-stem nucleus tractus solitarius (vagal afferent input) and the thoracic spinal cord. Accordingly, the potential exists for interaction in the central nervous system of inputs from the same thoracic organ. The esophagus and heart also possess an intrinsic nervous system with cell bodies in the organ wall or in ganglia in the epicardial fat.⁶

Further differences between somatic and visceral innervation relate to the density of innervation and spinal pattern of termination. In general, the number of visceral afferent fibers is disproportionately less than the number of somatic afferent fibers, although the rostrocaudal spread of visceral afferent fiber terminals in the spinal cord is considerably greater than the spread of central terminals from somatic afferent fibers. Although this means that there are fewer central visceral terminals in the spinal cord, visceral afferent fiber terminals have many more terminal swellings (suggestive of synapses) than somatic nociceptor terminals and they spread over several spinal cord segments.⁷ The obvious consequence of the low number of visceral afferents and greater intraspinal spread is loss of spatial discrimination, consistent with the diffuse, difficult-to-localize, nature of visceral pain.

The axons of visceral sensory neurons are, with rare exception, either thin, myelinated A δ fibers or unmyelinated C fibers. In general, A δ fibers, having some myelin, carry moderately fast impulses, usually of acute or sharp pain but also temperature. C fibers, without myelin, carry

slow impulses, usually of burning pain. Generally the proportion of A δ fibers in visceral sensory nerves is less than the proportion of C fibers. In addition, A δ fibers are fibers with a low threshold for response to mechanical stimulation, whereas C fibers have high thresholds; however, this is not universal.

Unlike tissue-damaging stimuli that produce pain in somatic structures, tissue injury is not required for production of pain in the viscera. For the lower airways, irritants contained in smoke, ammonia, and other inhaled substances are capable of producing discomfort and pain. For the heart and mesentery, ischemia can be an adequate stimulus.⁸ For hollow organs of the gastrointestinal tract, distention of the lumen of the organ, which activates stretch and tension receptors in the smooth muscles, is typically adequate.

Hollow viscera, including the esophagus, are innervated by two populations of mechanosensitive afferent fibers, namely a larger group (70% to 80%) of fibers that have low thresholds for response (i.e., within the physiologic range), and a smaller group (20% to 30%) of fibers that have thresholds for response that fall in the noxious range.⁹ All mechanosensitive visceral afferent fibers may function in some circumstances as nociceptors, and low- and high-threshold mechanosensitive fibers contribute to discomfort and pain that arise from the viscera.

Silent nociceptors, a relatively new category of receptor/afferent fibers, may also contribute to altered sensations from visceral structures.¹⁰ Silent nociceptors, more appropriately termed “mechanically insensitive afferents” have no spontaneous activity and do not respond to acute, high-intensity mechanical stimulation in normal circumstances. After tissue insult, mechanically insensitive afferents typically begin to discharge spontaneously and acquire sensitivity to mechanical stimulation. However, the contribution of such “silent” or “sleeping” afferent fibers to altered sensations that arise from the viscera is uncertain at present.^{11,12}

HYPERALGESIA

Some individuals are uniformly more sensitive (i.e., have lowered thresholds for stimulus-produced pain) than others. *Hyperalgesia*, the enhanced response to a stimulus that is normally noxious, consists of primary and secondary components. *Primary hyperalgesia* refers to enhanced sensitivity to stimuli applied at the site of tissue injury (e.g., an incision). *Secondary hyperalgesia*, conversely, pertains to enhanced sensitivity to stimuli applied to uninjured tissue adjacent to and occasionally distant from the site of injury. Peripheral mechanisms (sensitization of nociceptors and afferent fibers innervating the insulted tissue) and central mechanisms (changes in the excitability of spinal and supraspinal neurons) contribute to primary and secondary hyperalgesia, respectively. Afferent fibers that innervate the pelvic viscera have been shown to sensitize when organs are experimentally inflamed. After inflammation, both low-threshold and high-threshold mechanosensitive afferent fibers in the pelvic nerve exhibit exaggerated responses to distention relative to responses of the same afferent fibers before inflammation. This change in neuron excitability is believed to arise principally through the action of

glutamate at the *N*-methyl-D-aspartate receptor. Contributions of non-*N*-methyl-D-aspartate receptors, AMPA or kainate, and of the receptor at which substance P acts (neurokinin 1 receptor) are also likely.¹³ Glutamate and substance P are co-contained in many small-diameter dorsal root ganglion cells and presumably are concurrently released in the spinal dorsal horn, where *N*-methyl-D-aspartate receptors on nociceptor terminals may act as autoreceptors to facilitate the further release of both glutamate and substance P.¹⁴ In addition, there is evidence that substance P can act synergistically with glutamate to enhance the responses of spinal neurons.¹⁵

Virtually all spinal cord neurons that receive a visceral input also receive input from somatic structures, including the skin, muscle, and joints. This convergence of inputs in the spinal dorsal horn includes both viscerosomatic and viscerovisceral pathways and is believed to be the basis of the referred sensation that characterizes visceral pain. Such convergence suggests that injury to somatic tissue could lead to visceral hyperalgesia and, conversely, that injury to a viscus could lead to somatic hyperalgesia.

Spinal nociceptive transmission can be modulated by electrical or chemical stimulation in the midbrain or medulla.¹⁶ Both facilitatory and inhibitory influences on spinal nociceptive transmission are present and likely play an important role in the maintenance of secondary hyperalgesia.¹⁷ Electrical activation of vagal afferent fibers similarly engages descending facilitatory and inhibitory modulation of spinal nociceptive transmission. Responses of neurons in the thoracic dorsal horn to either esophageal distention¹⁸ or lower airway irritation caused by ammonia or smoke¹⁹ are altered when the cervical spinal cord is blocked or transected or when the vagi are cut. Responses to esophageal or respiratory stimulation would be expected to increase when the cervical spinal cord was blocked because tonic descending inhibitory influences are usually present; unexpectedly, responses were more commonly reduced, suggesting the presence of a descending facilitatory influence that is associated with vagal input to the brain stem. In a related work, both vagal afferent input and spinal cardiac nerve afferent inputs contribute to the sensation of cardiac pain, particularly referral of such pain to the neck and jaw.²⁰

MEASURING PAIN

Pain has proved to be both hard to define and difficult to measure. Because pain can be quantified only indirectly, it has been difficult to determine the optimal measuring tool for all types of pain sensations. Two widely used techniques, namely rating scales and questionnaires, are often used in clinical and epidemiologic studies of chest pain.

Rating scales constitute the simplest measurement of pain. One of the easiest to use is the quantification of pain intensity by a graded rating scale, such as the popular visual analogue scale.²¹ However, the sensation of pain has many more components than just its intensity; thus a single-dimensional rating scale leaves many aspects of the sensation undocumented.

To address the multidimensional qualities of pain, questionnaires have been developed.²² The McGill Pain Ques-

tionnaire, the most widely used method in the English language for studying the epidemiology of pain, was developed in the 1970s²³ and has been shown to be reliable and useful.²⁴ Although questionnaires are a powerful way of obtaining data on both the qualitative and the quantitative aspects of pain, it is not always possible to compare the results of studies with the same questionnaire because of differences in the way they have been employed.
